⁸ This conclusion relies on the mild assumption that the three-by-three matrices diagonalizing squark and slepton mass matrices are not so different from their fermionic partners. It has been shown that if this caveat is violated, then dimension five proton decay in minimal SUSY SU(5) may not be ruled out [56]. This is however a very fine-tuned resolution of the problem. Another possible way out is to allow for a more complicated SU(5) breaking Higgs sector in the otherwise minimal model [57]. I have also implicitly assumed a hierarchical structure for Yukawa matrices in this analysis. It is however possible to fine-tune a hierarchical structure for quarks and leptons which baffles the family structure. In this case it is possible to avoid the present constraints on minimal SUSY SU(5), for example see [58].

GUT models [59,27] the lifetime for the decay $\tau(p \to e^+\pi^0)$ can be near the excluded bound of 1×10^{34} years with, however, large model dependent and/or theoretical uncertainties. In other cases, the modes $p \to K^+\bar{\nu}$ and $p \to K^0\mu^+$ may be dominant [27]. To summarize, in either 4d or orbifold string/field theories, nucleon decay remains a premier signature for SUSY GUTs. Moreover, the observation of nucleon decay may distinguish extra-dimensional orbifold GUTs from four dimensional ones.

As a final note, in orbifold GUTs or string theory new discrete symmetries consistent with SUSY GUTs can forbid all dimension 3 and 4 baryon [B] and lepton [L] number violating operators and even forbid the mu term and dimension 5 B and L violating operators to all orders in perturbation theory [50]. The mu term and dimension 5 B and L violating operators may then be generated, albeit sufficiently suppressed, via non-perturbative effects. The simplest example of this is a Z_4^R symmetry which is the unique discrete R symmetry consistent with SO(10) [50]. In this case, proton decay is completely dominated by dimension 6 operators.

Before concluding the topic of baryon number violation, consider the status of $\Delta B=2$ neutron- anti-neutron oscillations. Generically the leading operator for this process is the dimension 9 six quark operator $G_{(\Delta B=2)}$ (u^c d^c d^c u^c d^c d^c) with dimensionful coefficient $G_{(\Delta B=2)} \sim 1/M^5$. The present experimental bound $\tau_{n-\bar{n}} \geq 0.86 \times 10^8$ sec. at 90% CL [60] probes only up to the scale $M \leq 10^6$ GeV. For $M \sim M_G$, $n-\bar{n}$ oscillations appear to be unobservable for any GUT (for a recent discussion see [61]).

15.1.6. Yukawa coupling unification:

15.1.6.1. 3rd generation, $b - \tau$ or $t - b - \tau$ unification:

If quarks and leptons are two sides of the same coin, related by a new grand unified gauge symmetry, then that same symmetry relates the Yukawa couplings (and hence the masses) of quarks and leptons. In SU(5), there are two independent renormalizable Yukawa interactions given by λ_t (10 10 5_H) + λ (10 $\bar{\bf 5}$ $\bar{\bf 5}_H$). These contain the SM interactions λ_t (Q u^c H_u) + λ (Q d^c H_d + e^c L H_d). Hence, at the GUT scale we have the tree level relation, $\lambda_b = \lambda_\tau \equiv \lambda$ [41]. In SO(10) there is only one independent renormalizable Yukawa interaction given by λ (16 16 10_H) which gives the tree level relation, $\lambda_t = \lambda_b = \lambda_\tau \equiv \lambda$ [62,63]. Note, in the discussion above we assume the minimal Higgs content with Higgs in $\bar{\bf 5}$, $\bar{\bf 5}$ for SU(5) and 10 for SO(10). With Higgs in higher dimensional representations there are more possible Yukawa couplings [75,76,77].

In order to make contact with the data, one now renormalizes the top, bottom and τ Yukawa couplings, using two loop RG equations, from M_G to M_Z . One then obtains the running quark masses $m_t(M_Z) = \lambda_t(M_Z) \ v_u, \quad m_b(M_Z) = \lambda_b(M_Z) \ v_d$ and $m_\tau(M_Z) = \lambda_\tau(M_Z) \ v_d$ where $< H_u^0 > \equiv v_u = \sin\beta \ v/\sqrt{2}, < H_d^0 > \equiv v_d = \cos\beta \ v/\sqrt{2}, v_u/v_d \equiv \tan\beta$ and $v \sim 246$ GeV is fixed by the Fermi constant, G_μ .

Including one loop threshold corrections at M_Z and additional RG running, one finds the top, bottom and τ pole masses. In SUSY, $b-\tau$ unification has two possible solutions with $\tan\beta\sim 1$ or 40-50. The small $\tan\beta$ solution is now disfavored by the LEP limit, $\tan\beta>2.4$ [64]. ⁹ The large $\tan\beta$ limit overlaps the SO(10) symmetry relation.

When $\tan \beta$ is large there are significant weak scale threshold corrections to down quark and charged lepton masses from either gluino and/or chargino loops [66]. Yukawa unification (consistent with low energy data) is only possible in a restricted region of SUSY parameter space with important consequences for SUSY searches [67]. More recent analyses of Yukawa unification can be found in Refs. [68,69,70,71]. There seems to be at least four possible choices of soft SUSY breaking parameters which fit the data, possibly more. Each case then leads to a distinct sparticle spectrum and phenomenology for LHC and dark matter experiments. They correspond to:

- universal squark and slepton masses (m_{16}) , universal A parameter (A_0) and gaugino masses $(M_{1/2})$, and non-universal Higgs masses (m_{H_u}, m_{H_d}) with "just-so" splitting [67,68].
- a universal squark and slepton mass term for the first two families $(m_{16_{1,2}})$ which is larger than the universal scalar mass for the third family (m_{16_3}) , universal A parameter (A_0) and gaugino masses $(M_{1/2})$ and universal Higgs mass term (m_{10}) . However all scalar masses then receive a D-term contribution to their masses given by the U(1) from SO(10) which commutes with SU(5). This is of the form

$$\begin{split} m_Q^2 &= m_E^2 = m_U^2 = m_{16}^2 + M_D^2, \\ m_D^2 &= m_L^2 = m_{16}^2 - 3 M_D^2, \\ m_{\bar{\nu}}^2 &= m_{16}^2 + 5 M_D^2, \\ m_{H_{u,d}}^2 &= m_{10}^2 \mp 2 M_D^2. \end{split}$$

This is the so-called "DR3 splitting" [69]. The R is associated with taking into account the renormalization group [RG] running of the right-handed neutrino from the GUT scale to the nominal value of its mass of order 10^{10-14} GeV, as indicated by light neutrino masses via the See-Saw mechanism. This RG running contributes to an additional splitting of the H_u and H_d masses [67].

- universal squark and slepton masses (m_0) , split Higgs masses and non-universal gaugino masses satisfying $(M_1 = \frac{3}{5}M_2 + \frac{2}{5}M_3)$, and $\mu, M_2 < 0$ [70], and
- universal squark and slepton mass term (m_{16}) , A parameter (A_0) , Higgs mass term (m_{10}) . All scalar masses then receive a D-term contribution to their masses given by the U(1) from SO(10) which commutes with SU(5), as above. Finally, non-universal gaugino masses satisfying $(M_3: M_2: M_1 = 2: -3: -1)$ with $M_3 > 0$ and $\mu < 0$ [71].

15.1.6.2. *Three families:*

Simple Yukawa unification is not possible for the first two generations of quarks and leptons. Consider the SU(5) GUT scale relation $\lambda_b = \lambda_\tau$. If extended to the first two generations one would have $\lambda_s = \lambda_\mu$, $\lambda_d = \lambda_e$ which gives $\lambda_s/\lambda_d = \lambda_\mu/\lambda_e$. The last relation is a renormalization group invariant and is thus satisfied at any scale. In particular, at the weak scale one obtains $m_s/m_d = m_\mu/m_e$ which is in serious disagreement with the data with $m_s/m_d \sim 20$ and $m_\mu/m_e \sim 200$. An elegant solution to this problem was given by Georgi and Jarlskog [72]. For a recent analysis in the context of supersymmetric GUTs, see Ref. [73]. Of course, a three family model must also give the observed CKM mixing in the quark sector. Note, although there are typically many more parameters in the GUT theory above M_G , it is possible to obtain effective low energy theories with many fewer parameters making strong predictions for quark and lepton masses.

Three family models which make significant predictions for low energy experiments have been constructed in the context of supersymmetric GUTs. It is important to note that grand unification alone is not sufficient to obtain predictive theories of fermion masses and mixing angles. Other ingredients are needed. In one approach additional global family symmetries are introduced (non-abelian family symmetries can significantly reduce the number of arbitrary parameters in the Yukawa matrices). These family symmetries constrain the set of effective higher dimensional fermion mass operators. In addition, sequential breaking of the family symmetry is correlated with the hierarchy of fermion masses. Three-family models exist which fit all the data, including neutrino masses and mixing [74]. In a completely separate approach for SO(10) models, the Standard Model Higgs bosons are contained in the higher dimensional Higgs representations including the 10, $\overline{126}$ and/or 120. Such theories have been shown to make predictions for neutrino masses and mixing angles [75-77]. A recent paper on this subject argues the necessity of split supersymmetry [78].

⁹ However, this bound disappears if one takes $M_{SUSY}=2$ TeV and $m_t=180$ GeV [65]. This apparent loop hole is now inconsistent with the observed top quark mass.

15.1.7. Neutrino Masses:

Atmospheric and solar neutrino oscillations, along with long baseline accelerator and reactor experiments, require neutrino masses. Adding three "sterile" neutrinos ν^c with the Yukawa coupling λ_{ν} (ν^c **L** $\mathbf{H_u}$), one easily obtains three massive Dirac neutrinos with mass $m_{\nu} = \lambda_{\nu} \ v_u.^{10}$ However in order to obtain a tau neutrino with mass of order 0.1 eV, one needs $\lambda_{\nu_{\tau}}/\lambda_{\tau} \leq 10^{-10}$. The see-saw mechanism, on the other hand, can naturally explain such small neutrino masses [79,80]. Since ν^c has no SM quantum numbers, there is no symmetry (other than global lepton number) which prevents the mass term $\frac{1}{2} \ \nu^c \ M \ \nu^c$. Moreover one might expect $M \sim M_G$. Heavy "sterile" neutrinos can be integrated out of the theory, defining an effective low energy theory with only light active Majorana neutrinos with the effective dimension 5 operator $\frac{1}{2}$ ($\mathbf{L} \ \mathbf{H_u}$) $\lambda_{\nu}^T \ M^{-1} \ \lambda_{\nu}$ ($\mathbf{L} \ \mathbf{H_u}$). This then leads to a 3×3 Majorana neutrino mass matrix $\mathbf{m} = m_{\nu}^T \ M^{-1} \ m_{\nu}$.

Atmospheric neutrino oscillations require neutrino masses with $\Delta m_{\nu}^2 \sim 3 \times 10^{-3} \ {\rm eV}^2$ with maximal mixing, in the simplest two neutrino scenario. With hierarchical neutrino masses $m_{\nu_{\tau}} = \sqrt{\Delta m_{\nu}^2} \sim 0.055 \ {\rm eV}$. Moreover via the "see-saw" mechanism $m_{\nu_{\tau}} = m_t (m_t)^2/(3M)$. Hence one finds $M \sim 2 \times 10^{14} \ {\rm GeV}$; remarkably close to the GUT scale. Note we have related the neutrino Yukawa coupling to the top quark Yukawa coupling $\lambda_{\nu_{\tau}} = \lambda_t$ at M_G as given in SO(10) or $SU(4) \times SU(2)_L \times SU(2)_R$. However at low energies they are no longer equal and we have estimated this RG effect by $\lambda_{\nu_{\tau}}(M_Z) \approx \lambda_t(M_Z)/\sqrt{3}$.

Neutrinos pose a special problem for SUSY GUTs. The question is why are the quark mixing angles in the CKM matrix small, while there are two large lepton mixing angles in the PMNS matrix. For a recent discussion of neutrino masses and mixing angles, see Refs. [81] and [82]. For SUSY GUT models which fit quark and lepton masses, see Ref. [74]. Finally, for a compilation of the range of SUSY GUT predictions for neutrino mixing, see [83].

15.1.8. Selected Topics:

15.1.8.1. Magnetic Monopoles:

In the broken phase of a GUT there are typically localized classical solutions carrying magnetic charge under an unbroken U(1)symmetry [84]. These magnetic monopoles with mass of order M_G/α_G are produced during the GUT phase transition in the early universe. The flux of magnetic monopoles is experimentally found to be less than $\sim 10^{-16} \, {\rm cm}^{-2} \, {\rm s}^{-1} \, {\rm sr}^{-1}$ [85]. Many more are however predicted, hence the GUT monopole problem. In fact, one of the original motivations for an inflationary universe is to solve the monopole problem by invoking an epoch of rapid inflation after the GUT phase transition [86]. This would have the effect of diluting the monopole density as long as the reheat temperature is sufficiently below M_G . Other possible solutions to the monopole problem include: sweeping them away by domain walls [87], U(1) electromagnetic symmetry breaking at high temperature [88] or GUT symmetry non-restoration [89]. Parenthetically, it was also shown that GUT monopoles can catalyze nucleon decay [90]. A significantly lower bound on the monopole flux can then be obtained by considering X-ray emission from radio pulsars due to monopole capture and the subsequent nucleon decay catalysis [91].

15.1.8.2. Baryogenesis via Leptogenesis:

Baryon number violating operators in SU(5) or SO(10) preserve the global symmetry B-L. Hence the value of the cosmological B-L density is an initial condition of the theory and is typically assumed to be zero. On the other hand, anomalies of the electroweak symmetry violate B+L while also preserving B-L. Hence thermal fluctations in the early universe, via so-called sphaleron processes, can drive B+L to zero, washing out any net baryon number generated in the early universe at GUT temperatures.

One way out of this dilemma is to generate a net B-L dynamically in the early universe. We have just seen that neutrino oscillations suggest a new scale of physics of order 10^{14} GeV. This scale is associated with heavy Majorana neutrinos with mass M. If in the early universe, the decay of the heavy neutrinos is out of equilibrium and violates both lepton number and CP, then a net lepton number may be generated. This lepton number will then be partially converted into baryon number via electroweak processes [92].

15.1.8.3. *GUT symmetry breaking:*

The grand unification symmetry is necessarily broken spontaneously. Scalar potentials (or superpotentials) exist whose vacua spontaneously break SU(5) and SO(10). These potentials are ad hoc (just like the Higgs potential in the SM) and therefore it is hoped that they may be replaced with better motivated sectors. Gauge coupling unification now tests GUT breaking sectors, since it is one of the two dominant corrections to the GUT threshold correction ϵ_3 . The other dominant correction comes from the Higgs sector and doublet-triplet splitting. This latter contribution is always positive $\epsilon_3 \propto \ln(M_T/M_G)$ (where M_T is an effective color triplet Higgs mass), while the low energy data typically requires $\epsilon_3 < 0$. Hence the GUT breaking sector must provide a significant (of order -8%) contribution to ϵ_3 to be consistent with the Super-K bound on the proton lifetime [35,26,36,74].

In string theory (and GUTs in extra-dimensions), GUT breaking may occur due to boundary conditions in the compactified dimensions [8,11]. This is still ad hoc. The major benefit is that it does not require complicated GUT breaking sectors.

15.1.8.4. Doublet-triplet splitting:

The minimal supersymmetric standard model has a μ problem; why is the coefficient of the bilinear Higgs term in the superpotential μ ($\mathbf{H_u} \; \mathbf{H_d}$) of order the weak scale when, since it violates no low energy symmetry, it could be as large as M_G . In a SUSY GUT, the μ problem is replaced by the problem of doublet-triplet splitting – giving mass of order M_G to the color triplet Higgs and mass μ to the Higgs doublets. Several mechanisms for natural doublet-triplet splitting have been suggested, such as the sliding singlet [93], missing partner or missing VEV [94], and pseudo-Nambu-Goldstone boson mechanisms. Particular examples of the missing partner mechanism for SU(5) [36], the missing VEV mechanism for SO(10) [74,26] and the pseudo-Nambu-Goldstone boson mechanism for SU(6) [95] have been shown to be consistent with gauge coupling unification and proton decay. There are also several mechanisms for explaining why μ is of order the SUSY breaking scale [96]. Finally, for a recent review of the μ problem and some suggested solutions in SUSY GUTs and string theory, see Ref. [97,10,98,50] and references therein.

Once again, in string theory (and orbifold GUTs), the act of breaking the GUT symmetry via orbifolding projects certain states out of the theory. It has been shown that it is possible to remove the color triplet Higgs while retaining the Higgs doublets in this process. Hence the doublet-triplet splitting problem is finessed. As discussed earlier (see Sec. 15.1), this can have the effect of eliminating the contribution of dimension 5 operators to nucleon decay.

15.1.9. String theory:

String theory has made significant progress in locating the minimal supersymmetric standard model [MSSM] in the string landscape. Random searches for MSSM-like models have found some success, see for example Ref. 99. However, recently a solid leap forward has been made by imposing a supersymmetric GUT locally in the extra dimensions of the string. Many MSSM-like models have been found in $E(8) \times E(8)$ heterotic orbifold constructions [100–103] or more recently on smooth Calabi-Yau three-folds [104]. See also in F theory constructions [105–107]. There appear, however, to be some problems associated with large threshold corrections to gauge coupling unification in the F theory constructions which make use of a non-vanishing hypercharge field strength to break SU(5)to $SU(3)_C \times SU(2)_L \times U(1)_Y$ [108]. Nevertheless, a SUSY GUT guarantees the correct particle content of the Standard Model and also allows for reasonable looking hierarchical Yukawa matrices. For a more detailed discussion, see [109].

¹⁰ Note, these "sterile" neutrinos are quite naturally identified with the right-handed neutrinos necessarily contained in complete families of SO(10) or Pati-Salam.

15.2. Conclusion

Grand unification of the strong and electroweak interactions requires that the three low energy gauge couplings unify (up to small threshold corrections) at a unique scale, M_G . Supersymmetric grand unified theories provide, by far, the most predictive and economical framework allowing for perturbative unification.

The three pillars of SUSY GUTs are:

- gauge coupling unification at $M_G \sim 3 \times 10^{16}$ GeV;
- low-energy supersymmetry [with a large SUSY desert], and
- nucleon decay.

The first prediction has already been verified (see Fig. Fig. 15.1). Perhaps the next two will soon appear. Whether or not Yukawa couplings unify is more model dependent. Nevertheless, the "digital" 16 dimensional representation of quarks and leptons in SO(10) is very compelling and may yet lead to an understanding of fermion masses and mixing angles.

In any event, the experimental verification of the first three pillars of SUSY GUTs would forever change our view of Nature. Moreover, the concomitant evidence for a vast SUSY desert would expose a huge lever arm for discovery. For then it would become clear that experiments probing the TeV scale could reveal physics at the GUT scale and perhaps beyond. Of course, some questions will still remain: Why do we have three families of quarks and leptons? How is the grand unified symmetry and possible family symmetries chosen by Nature? At what scale might stringy physics become relevant? Etc.

16. HEAVY-QUARK AND SOFT-COLLINEAR EFFECTIVE THEORY

Written August 2011 by C.W. Bauer (LBNL) and M. Neubert (U. Mainz).

16.1. Effective Field Theories

Quantum field theories represent the most precise computational tool for describing physics at the highest energies. One of their characteristic features is that they almost inevitably involve multiple length scales. When trying to determine the value of an observable, quantum field theory demands that all possible virtual states and hence all particles be included in the calculation. Since these particles have widely different masses, the final prediction is sensitive to many scales. This fact represents a formidable challenge from a practical point of view. No realistic quantum field theories can be solved exactly, so that one has to resort to approximation schemes; these, however, are typically most straightforward when only a single scale is involved at a time.

Effective field theories (EFTs) provide a general theoretical framework to deal with the multi-scale problems of realistic quantum field theories. This framework aims to reduce such problems to a combination of separate and simpler single-scale problems; simultaneously, however, it provides an organizational scheme whereby the other scales are not omitted but allowed to play their role in a separate step of the computation. The philosophy and basic principles of this approach are very generic, and correspondingly EFTs represent a widely used method in many different areas of high-energy physics, from the low energy scales of atomic and nuclear physics to the high energy scales of (partly yet unknown) elementary particle physics. EFTs can play a role both within analytic perturbative computations and in the context of non-perturbative numerical simulations; see [1–3] for some early references. One of the simplest applications of EFTs to particle physics is to describe an underlying theory that is only probed at energy scales $E < \Lambda$. Any particle with mass $m > \Lambda$ cannot be produced as a real state and therefore only leads to short-distance virtual effects. Thus, one can construct an effective theory in which the quantum fluctuations of such heavy particles are "integrated out" from the generating functional integral for Green functions. This results in a simpler theory containing only those degrees of freedom that are relevant to the energy scales under consideration. In fact, the standard model of particle physics itself is widely viewed as an EFT of some vet unknown, more fundamental theory.

The development of any effective theory starts by identifying the degrees of freedom that are relevant to describe the physics at a given energy (or length) scale, and constructing the Lagrangian describing the interactions among these fields. Short-distance quantum fluctuations associated with much smaller length scales are absorbed into the coefficients of the various operators in the effective Lagrangian. These coefficients are determined in a matching procedure, by requiring that the EFT reproduces the matrix elements of the full theory up to power corrections. In many cases the effective Lagrangian exhibits enhanced symmetries compared with the fundamental theory, allowing for simple and sometimes striking predictions relating different observables.

16.2. Heavy-Quark Effective Theory

Heavy-quark systems provide prime examples for applications of the EFT technology, because the hierarchy $m_Q\gg\Lambda_{\rm QCD}$ (with Q=b,c) provides a natural separation of scales. Physics at the scale m_Q is of a short-distance nature and can be treated perturbatively, while for heavy-quark systems there is always also some hadronic physics governed by the confinement scale $\Lambda_{\rm QCD}$. Being able to separate the short-distance and long-distance effects associated with these two scales is crucial for any quantitative description in heavy-quark physics. For instance, if the long-distance hadronic matrix elements are obtained from lattice QCD, then it is necessary to analytically compute the short-distance effects, which come from short-wavelength modes that do not fit on present-day lattices. In many other instances, the long-distance hadronic physics can be encoded in a small number of universal parameters.

16.2.1. General idea and derivation of the effective

Lagrangian: The simplest effective theory for heavy-quark systems is the heavy-quark effective theory (HQET) [4–7] (see [8,9] for detailed discussions). It provides a simplified description of the soft interactions of a single heavy quark interacting with soft, light partons. This includes the interactions that bind the heavy quark with other light partons inside heavy mesons (B, B^*, \ldots) and baryons $(\Lambda_b, \Sigma_b, \ldots)$.

A softly interacting heavy quark is nearly on-shell. Its momentum may be decomposed as $p_Q=m_Qv+k$, where v is the 4-velocity of the hadron containing the heavy quark, and the "residual momentum" $k\sim \Lambda_{\rm QCD}$ results from the soft interactions of the heavy quark with its environment. In the limit $m_Q\gg \Lambda_{\rm QCD}$, the soft interactions do not change the 4-velocity of the heavy quark, which is therefore a conserved quantum number that is often used as a label on the effective heavy-quark fields. A nearly on-shell Dirac spinor has two large and two small components. We define

$$Q(x) = e^{-im_Q v \cdot x} \left[h_v(x) + H_v(x) \right], \tag{16.1}$$

where

$$h_v(x) = e^{im_Q v \cdot x} \frac{1 + \not p}{2} Q(x), \qquad H_v(x) = e^{im_Q v \cdot x} \frac{1 - \not p}{2} Q(x)$$
 (16.2)

are the large ("upper") and small ("lower") components of the Dirac spinor, respectively. The extraction of the phase factor in Eq. (16.1) implies that the fields h_v and H_v carry the residual momentum k. These fields obey the projection relations $\phi h_v = h_v$ and $\phi H_v = -H_v$. Inserting these definitions into the Dirac Lagrangian yields

$$\mathcal{L}_{Q} = \bar{h}_{v} iv \cdot D h_{v} + \bar{H}_{v} (-iv \cdot D - 2m_{Q}) H_{v} + \bar{h}_{v} i \vec{\not D} H_{v} + \bar{H}_{v} i \vec{\not D} h_{v}, \quad (16.3)$$

where $i\vec{D}^{\mu}=iD^{\mu}-v^{\mu}\,iv\cdot D$ is the "spatial" covariant derivative (note that $v^{\mu}=(1,\vec{0})$ in the heavy-hadron rest frame). The interpretation of Eq. (16.3) is that the field h_v describes a massless fermion, while H_v describes a heavy fermion with mass $2m_Q$. Both modes are coupled to each other via the last two terms. Soft interactions cannot excite the heavy fermion, so we integrate it out from the generating functional of the theory. The light field which remains describes the fluctuations of the heavy quark about its mass shell. Solving the classical equation of motion for the field H_v yields

$$H_{v} = \frac{1}{2m_{Q} + iv \cdot D} i \vec{\not}D h_{v} = \frac{1}{2m_{Q}} \sum_{n=0}^{\infty} \left(-\frac{iv \cdot D}{2m_{Q}} \right)^{n} i \vec{\not}D h_{v} , \quad (16.4)$$

which implies $H_v = O(\Lambda_{\rm QCD}/m_Q)\,h_v$, provided the residual momenta are small. The effective Lagrangian of HQET is obtained by inserting this result into Eq. (16.3). At subleading order in $1/m_Q$ one finds

$$\mathcal{L}_{\text{HQET}} = \bar{h}_v \, iv \cdot D_s \, h_v + \frac{1}{2m_Q} \times$$

$$\left[\bar{h}_v(i\vec{D}_s)^2 h_v + C_{\text{mag}}(\mu) \frac{g}{2} \bar{h}_v \,\sigma_{\mu\nu} \,G_s^{\mu\nu} h_v\right] + \dots \,. \tag{16.5}$$

Note that the covariant derivative $iD_s^\mu=i\partial^\mu+gA_s^\mu$ contains only the soft gluon field. Hard gluons have been integrated out, and their effects are contained in the Wilson coefficients of the various operators in the effective Lagrangian. From the leading operator one derives the Feynman rules of HQET. The new operators entering at subleading order are referred to as the "kinetic energy" and "chromo-magnetic interaction". The kinetic-energy operator corresponds to the first correction term in the Taylor expansion of the relativistic energy $E=m_Q+\vec{p}^2/2m_Q+\ldots$ Lorentz invariance, which is encoded as a reparametrization invariance of the effective Lagrangian [10], ensures that its Wilson coefficient is not renormalized $(C_{\rm kin}\equiv 1)$. The coefficient of the chromo-magnetic operator, $C_{\rm mag}(\mu)=1+\mathcal{O}(\alpha_s)$, receives corrections starting at one-loop order.

16.2.2. Spin-flavor symmetry and applications in

spectroscopy: The leading term in the HQET Lagrangian exhibits a global spin-flavor symmetry. Its physical meaning is that, in the infinite mass limit, the properties of hadronic systems containing a single heavy quark are insensitive to the spin and flavor of the heavy quark [11,12]. The spin symmetry results from the fact that there appear no Dirac matrices in the leading term in the effective Lagrangian Eq. (16.5), implying that the interactions of the heavy quark with soft gluons leave its spin unchanged. The flavor symmetry arises since the mass of the heavy quark does not appear at leading order. When there are n_Q heavy quarks moving at the same velocity, one can simply extend Eq. (16.5) by summing over n_Q identical terms for heavy-quark fields h_v^i . The result is invariant under rotations in flavor space. When combined with the spin symmetry, the symmetry group becomes promoted to $SU(2n_Q)$. The flavor symmetry is broken by the operators arising at order $1/m_Q$ and higher. However, at first order only the chromo-magnetic operator breaks the spin symmetry.

The spin-flavor symmetry leads to many interesting relations between the properties of hadrons containing a heavy quark. The most direct consequences concern the spectroscopy of such states [13]. In the heavy-quark limit, the spin of the heavy quark and the total angular momentum j of the light degrees of freedom are separately conserved by the strong interactions. Because of heavyquark symmetry, the dynamics is independent of the spin and mass of the heavy quark. Hadronic states can thus be classified by the quantum numbers (flavor, spin, parity, etc.) of the light degrees of freedom. The spin symmetry predicts that, for fixed $j \neq 0$, there is a doublet of degenerate states with total spin $J = j \pm 1/2$. The flavor symmetry relates the properties of states with different heavy quark flavor. In the case of the ground-state mesons containing a heavy quark, the light degrees of freedom have the quantum numbers of an antiquark, and the degenerate states are the pseudoscalar (J=0) and vector (J=1) mesons. Their masses are split by hyperfine corrections of order $1/m_Q$, such that one expects $m_{B^*}-m_B=O(1/m_b)$ and $m_{D^*}-m_D=O(1/m_c)$. It follows that $m_{B^*}^2-m_B^2\simeq m_{D^*}^2-m_D^2\simeq {\rm const.}$ The data are compatible with this result: $m_{B^*}^2-m_B^2\simeq 0.49\,{\rm GeV^2}$ and $m_{D^*}^2-m_D^2\simeq 0.55\,{\rm GeV^2}$.

16.2.3. Weak decay form factors: Of particular interest are the relations between the weak decay form factors of heavy mesons, which parametrize hadronic matrix elements of currents between two meson states containing a heavy quark. These relations have been derived by Isgur and Wise [12], generalizing ideas developed by Nussinov and Wetzel [14] and Voloshin and Shifman [15]. For the purpose of this discussion, it is convenient to work with a mass-independent normalization of meson states and use velocity rather than momentum variables.

Consider the elastic scattering of a pseudoscalar meson, $P(v) \to P(v')$, induced by an external vector current coupled to the heavy quark contained in P, which acts as a color source moving with the meson's velocity v. The action of the current is to replace instantaneously the color source by one moving at velocity v'. Soft gluons need to be exchanged in order to rearrange the light degrees of freedom and build the final state meson moving at velocity v'. This rearrangement leads to a form factor suppression. The important observation is that, in the $m_Q \to \infty$ limit, the form factor can only depend on the Lorentz boost $\gamma = v \cdot v'$ connecting the rest frames of the initial and final-state mesons (as long as $\gamma = \mathcal{O}(1)$). In the effective theory, which provides the appropriate framework to consider the limit $m_Q \to \infty$ with the quark velocities kept fixed, the hadronic matrix element describing the scattering process can be written as

$$\langle P(v')|\bar{h}_{v'}\gamma^{\mu}h_{v}|P(v)\rangle = \xi(v\cdot v')(v+v')^{\mu},\tag{16.6}$$

with a form factor $\xi(v \cdot v')$ that is real and does not depend on m_Q . By flavor symmetry, the form factor remains identical when one replaces the heavy quark Q in one of the meson states by a heavy quark Q' of a different flavor, thereby turning P into another pseudoscalar meson P'. At the same time, the current becomes a flavor-changing vector current. This universal form factor is called the Isgur-Wise function [12]. For equal velocities the vector current $J^{\mu} = \bar{h}_v \gamma^{\mu} h_v$ is conserved in the effective theory, irrespective of the

flavor of the heavy quarks. The corresponding conserved charges are the generators of the flavor symmetry. It follows that the Isgur-Wise function is normalized at the point of equal velocities: $\xi(1)=1$. Since $E_{\rm recoil}=m_{P'}(v\cdot v'-1)$ is the recoil energy of the daughter meson P' in the rest frame of the parent meson P, the point $v\cdot v'=1$ is referred to as the zero recoil limit. The heavy-quark spin symmetry leads to additional relations among weak decay form factors. It can be used to relate matrix elements involving vector mesons to those involving pseudoscalar mesons, which once again can be described completely in terms of the universal Isgur-Wise function.

These form factor relations imposed by heavy-quark symmetry describe the semileptonic decay processes $\bar{B} \to D \, \ell \, \bar{\nu}$ and $\bar{B} \to D^* \ell \, \bar{\nu}$ in the limit of infinite heavy-quark masses. They are model-independent consequences of QCD. The known normalization of the Isgur-Wise function at zero recoil can be used to obtain a model-independent measurement of the element $|V_{cb}|$ of the Cabibbo-Kobayashi-Maskawa (CKM) matrix. The semileptonic decay $\bar{B} \to D^* \ell \, \bar{\nu}$ is ideally suited for this purpose [16]. Experimentally, this is a particularly clean mode, since the reconstruction of the D^* meson mass provides a powerful rejection against background. From the theoretical point of view, it is ideal since the decay rate at zero recoil is protected by Luke's theorem against first-order power corrections in $1/m_Q$ [17]. This is described in more detail in Section 11 of the PDG Book.

16.2.4. Decoupling transformation: At leading order in $1/m_Q$, the couplings of soft gluons to heavy quarks in the effective Lagrangian Eq. (16.5) can be removed by the field redefinition $h_v(x) = Y_v(x) \, h_v^{(0)}(x)$, where $Y_v(x)$ denotes a time-like Wilson line along the direction of v, extending from minus infinity to the point x. In terms of the new fields, the HQET Lagrangian becomes

$$\mathcal{L}_{\text{HOET}} = \bar{h}_v^{(0)} i v \cdot \partial h_v^{(0)} + O(1/m_Q). \tag{16.7}$$

At leading order in $1/m_Q$, this is a free theory as far as the strong interactions of heavy quarks are concerned. However, the theory is nevertheless non-trivial in the presence of external sources. Consider, e.g., the case of a weak-interaction heavy-quark current

$$\bar{h}_{v'}\gamma^{\mu}(1-\gamma_5)h_v = \bar{h}_{v'}^{(0)}\gamma^{\mu}(1-\gamma_5)Y_{v'}^{\dagger}Y_v h_v^{(0)}, \qquad (16.8)$$

where v and v' are the velocities of the heavy mesons containing the heavy quarks. Unless the two velocities are equal, the object $Y_{v'}^{\dagger}Y_v$ is non-trivial, and hence the soft gluons do not decouple from the heavy quarks inside the current operator. One may interpret $Y_{v'}^{\dagger}Y_v$ as a Wilson loop with a cusp at the point x, where the two paths parallel to the different velocity vectors intersect. The presence of the cusp leads to non-trivial ultra-violet behavior (for $v \neq v'$), which is described by a cusp anomalous dimension $\Gamma_c(v \cdot v')$ that was calculated at two-loop order in [18]. It coincides with the velocity-dependent anomalous dimension of heavy-quark currents, which was rediscovered later in the context of HQET [19]. The interpretation of heavy quarks as Wilson lines is a useful tool, which was put forward in some of the very first papers on the subject [4]. This technology will be useful in the study of the interactions of heavy quarks with collinear degrees of freedom discussed later in this review.

16.2.5. Heavy-quark expansion for inclusive decays: The theoretical description of inclusive decays of hadrons containing a heavy quark exploits two observations [20–24]: bound-state effects related to the initial state can be calculated using the heavy-quark expansion, and the fact that the final state consists of a sum over many hadronic channels eliminates the sensitivity to the properties of individual final-state hadrons. The second feature rests on the hypothesis of quark-hadron duality, i.e. the assumption that decay rates are calculable in QCD after a smearing procedure has been applied [25]. In semileptonic decays, the integration over the lepton spectrum provides a smearing over the invariant hadronic mass of the final state (global duality). For nonleptonic decays, where the total hadronic mass is fixed, the summation over many hadronic final states provides an averaging (local duality).

Using the optical theorem, the inclusive decay width of a hadron H_b containing a b quark can be written in the form

$$\Gamma(H_b) = \frac{1}{M_{H_b}} \operatorname{Im} \langle H_b | i \int d^4 x \, T \left\{ \mathcal{H}_{\text{eff}}(x), \mathcal{H}_{\text{eff}}(0) \right\} | H_b \rangle. \tag{16.9}$$

The effective weak Hamiltonian for b-quark decays consists of dimension-6 four-fermion operators and dipole operators [80]. It follows that the leading contributions to the inclusive decay rate in Eq. (16.9) arise from two-loop diagrams. Because of the large mass of the b quark, the momenta flowing through the internal propagators are large. It is thus possible to construct an operator-product expansion (OPE) for the transition operator, in which it is represented as a series of local operators containing two b-quark fields. The operator with the lowest dimension is $\bar{b}b$. The next non-trivial operator has dimension 5 and contains the gluon field. It arises from diagrams in which a soft gluon is emitted from one of the internal lines of the two-loop diagrams. From dimension 6 on, an increasing number of operators appears. For dimensional reasons, the matrix elements of higher-dimensional operators are suppressed by inverse powers of the b-quark mass. Thus, the total inclusive decay rate of a hadron H_b can be written as [21,47]

$$\Gamma(H_b) = \frac{G_F^2 m_b^5 |V_{cb}|^2}{192 \pi^3} \times$$

$$\left\{c_3 \langle \bar{b}b \rangle + c_5 \frac{\langle \bar{b} g \sigma_{\mu\nu} G^{\mu\nu} b \rangle}{m_b^2} + \sum_n c_6^{(n)} \frac{\langle O_6^{(n)} \rangle}{m_b^3} + \ldots \right\}, \qquad (16.10)$$

where the prefactor arises from the loop integrations, c_i are calculable coefficient functions, and $\langle O_i \rangle$ are the (normalized) forward matrix elements between H_b states. These matrix elements can be systematically expanded in powers of $1/m_b$ using HQET. The result is [21,47]

$$\langle \bar{b}b \rangle = 1 - \frac{\mu_{\pi}^2(H_b) - \mu_G^2(H_b)}{2m_b^2} + \dots, \qquad \frac{\langle \bar{b} \, g \sigma_{\mu\nu} G^{\mu\nu} b \rangle}{m_b^2} = \frac{2\mu_G^2(H_b)}{m_b^2} + \dots,$$

$$(16.11)$$

where $\mu_{\pi}^2(H_b)$ and $\mu_G^2(H_b)$ are the matrix elements of the heavy-quark kinetic energy and chromomagnetic interaction inside the hadron H_b , respectively [27]. For the ground-state heavy mesons and baryons, one can extract $\mu_G^2(B) = 3(m_{B^*}^2 - m_B^2)/4 \simeq 0.36\,\mathrm{GeV}^2$ and $\mu_G^2(\Lambda_b) = 0$ from spectroscopy.

From the fully inclusive width Eq. (16.10) one can obtain the lifetime of a heavy hadron via $\tau(H_b)=1/\Gamma(H_b)$. Due to the universality of the leading term in the heavy-quark expansion, lifetime ratios such as $\tau(B^-)/\tau(\bar{B}^0)$, $\tau(\bar{B}^0_s)/\tau(\bar{B}^0)$, and $\tau(\Lambda_b)/\tau(\bar{B}^0)$ are particularly sensitive to the hadronic parameters determining the power corrections in the expansion. In order to understand these ratios theoretically, it is necessary to include phase-space enhanced power corrections of order $(\Lambda_{\rm QCD}/m_b)^3$ as well as short-distance perturbative effects in the calculation [28,29].

A formula analogous to Eq. (16.10) can be derived for differential distributions in specific inclusive decay processes, assuming that these distributions are integrated over sufficiently large portions of phase space to ensure quark-hadron duality. Important examples are the distributions in lepton energy $(d\Gamma/dE_\ell)$ or lepton invariant mass $(d\Gamma/dq^2)$, as well as moments of the invariant hadronic mass distribution, in the semileptonic processes $\bar{B} \to X_u \, \ell \, \bar{\nu}$ and $\bar{B} \to X_c \, \ell \, \bar{\nu}$, as well as the photon energy spectrum $(d\Gamma/dE_\gamma)$ in the radiative process $\bar{B} \to X_s \gamma$. While the latter process is primarily used to test the Standard Model and search for hints of new physics, an analysis of decay distributions in the semileptonic processes can be employed to perform a global fit determining the CKM matrix elements $|V_{ub}|$ and $|V_{cb}|$ along with heavy-quark parameters such as the masses m_b, m_c and the hadronic parameters $\mu_\pi^2(B)$, $\mu_G^2(B)$. These determinations provide some of the most accurate values for these parameters [30].

16.2.6. Shape functions and non-local power corrections: In certain regions of phase space, in which the hadronic final state in an inclusive heavy-hadron decay is made up of light energetic partons, the local OPE for inclusive decays must be replaced by a more complicated expansion involving hadronic matrix elements of non-local light-ray operators [52,53]. Prominent examples are the radiative decay $\bar{B} \to X_s \gamma$ for large photon energy E_γ near $m_B/2$, and the semileptonic decay $\bar{B} \to X_u \ell \bar{\nu}$ at large lepton energy or small hadronic invariant mass. In these cases, the differential decay rates at leading order in the heavy-quark expansion can be written in the factorized form $d\Gamma \propto H \, J \otimes S$ [33], where the hard function H and the jet function J are calculable in perturbation theory. The characteristic scales for these functions are set by m_b and $(m_b \Lambda_{\rm QCD})^{1/2}$, respectively. The soft function

$$S(\omega) = \int \frac{dt}{4\pi} e^{-i\omega t} \langle \bar{B}(v) | \bar{h}_v(tn) Y_n(tn) Y_n^{\dagger}(0) h_v(0) | \bar{B}(v) \rangle \quad (16.12)$$

is a genuinely non-perturbative object, called the shape function [52,53]. Here Y_n are soft Wilson lines along a light-like direction n aligned with the momentum of the hadronic final-state jet. The jet function and the shape function share a common variable $\omega \sim \Lambda_{\rm QCD}$, and the symbol \otimes denotes a convolution in this variable.

While the hard function is different for the two decays, the jet and soft functions are identical at leading order in $\Lambda_{\rm QCD}/m_Q$. This is particularly important for the soft function. It is this shape function that introduces non-perturbative physics into the theoretical predictions for the cross sections of $\bar{B} \to X_s \gamma$ and $\bar{B} \to X_u \, \ell \bar{\nu}$ in the regions of experimental interest. The fact that both decays depend on the same non-perturbative function made it possible to determine this non-perturbative information from the measured shape of the photon spectrum in $\bar{B} \to X_s \gamma$, allowing for a better understanding of the process used to determine the CKM element $|V_{ub}|$. In higher orders of the heavy-quark expansion, an increasing number of subleading jet and soft functions is required to describe the decay distributions [34]. These have been analyzed in detail at order $1/m_b$ [35–37]. The technology for deriving the corresponding factorization theorems relies on SCET, which is discussed below.

16.3. Soft-Collinear Effective Theory

As discussed in the previous section, soft gluons that bind a heavy quark inside a heavy meson cannot change the virtuality of that heavy quark by a significant amount. The ratio of $\Lambda_{\rm QCD}/m_Q$ provided the expansion parameter in HQET, which is a small parameter since $m_Q\gg\Lambda_{\rm QCD}$. This obviously does not work when considering light quarks. However, if the energy Q of the quarks is large, the ratio $\Lambda_{\rm QCD}/Q$ provides a small parameter which can be used to construct an effective theory. One major difference to HQET is that light energetic quarks cannot only emit soft gluons, but they can also emit collinear gluons (an energetic gluon in the same direction as the original quark), without parametrically changing their virtuality. Thus, to fully reproduce the long-distance physics of energetic quarks requires that one includes their interactions with both soft and collinear particles. The resulting effective theory is therefore called soft-collinear effective theory (SCET) [38–40].

SCET is applicable for processes containing particles with energy much in excess of their mass, and it has therefore a wide range of applications. In this brief review we will outline the main features of this effective theory and mention a few selected applications.

16.3.1. General idea of the expansion: Consider a quark with energy Q and virtuality $m \ll Q$, moving along the direction \vec{n} . It is convenient to parameterize the momentum p_n of this particle in terms of its light-cone components, defined by $(p_n^-, p_n^+, p_n^\perp) = (\bar{n} \cdot p_n, n \cdot p_n, p_n^\perp)$, where $n^\mu = (1, \vec{n})$ and $\bar{n}^\mu = (1, -\vec{n})$ are light-like 4-vectors, and $n \cdot p_\perp = \bar{n} \cdot p_\perp = 0$. A subscript n has been added to the momentum to identify it as a collinear particle in direction n (more precisely, a particle with energy much larger than its virtuality moving along a direction \vec{n}). In terms of these light-cone components, the virtuality satisfies $m^2 = p_n^+ p_n^- + p_n^{\perp 2}$. The individual components of the momentum satisfy

$$(p_n^-, p_n^+, p_n^\perp) \sim (Q, m^2/Q, m) \equiv Q(1, \lambda^2, \lambda),$$
 (16.13)

where $\lambda = m/Q$ is the expansion parameter of SCET.

The virtuality of such an energetic particle remains parametrically unchanged if it interacts with energetic particles in the same direction n, or with soft particles with momentum scaling as

$$(p_s^-, p_s^+, p_s^\perp) \sim Q(\lambda^2, \lambda^2, \lambda^2).$$
 (16.14)

Thus, it is the interactions of collinear and soft degrees of freedom that give rise to the long-distance physics. SCET, which is constructed to reproduce this long-distance dynamics, is therefore an effective theory describing the interactions of collinear and soft particles.

The above power counting treats the soft momentum to be of order m^2/Q , where m denotes the mass of a collinear system. If the mass of the collinear system is of order $\Lambda_{\rm QCD}$, as would be the case for a single energetic hadron, this power counting is no longer applicable, since $\Lambda_{\rm QCD}$ provides a natural cutoff to QCD and the soft momentum cannot be below this scale. To describe such systems requires a modified version of SCET, called SCET_{II}, in which the scaling of the soft modes is $Q(\lambda, \lambda, \lambda)$. In this review we will focus only on SCET with the scaling discussed before, which is sometimes called SCET_I.

16.3.2. Leading-order Lagrangian: The derivation of the SCET Lagrangian follows similar steps as the derivation of the HQET Lagrangian in Section 16.2.1, but care has to be taken to properly account for the interactions of collinear fields with one another. We begin by deriving the Lagrangian for a theory containing only a single type of collinear degrees of freedom. We are interested in the interactions of fermion fields $q_n(x)$ with gluon fields $A_n(x)$, which have collinear momentum in the same light-like direction n. Similar to HQET, one can separate the full QCD field into two components, $q_n(x) = \psi_n(x) + \Xi_n(x)$, where

$$\psi_n(x) = \frac{n \overline{n}}{4} q_n(x), \qquad \Xi_n(x) = \frac{\overline{n} n}{4} q_n(x).$$

In terms of these fields, the QCD Lagrangian is

$$\mathcal{L}_{n} = \bar{\psi}_{n}(x)\frac{\vec{\eta}}{2}in \cdot D_{n}\,\psi_{n}(x) + \bar{\Xi}_{n}(x)\frac{\vec{\eta}}{2}i\bar{n} \cdot D_{n}\,\Xi_{n}(x) + \bar{\psi}_{n}(x)i\,\mathcal{D}_{n}^{\perp}\,\Xi_{n}(x) + \bar{\Xi}_{n}(x)i\,\mathcal{D}_{n}^{\perp}\,\psi_{n}(x),$$

$$(16.15)$$

where we have defined the transverse derivative $D_n^{\perp \mu} = D_n^{\mu} - \frac{n^{\mu}}{2}\bar{n} \cdot D_n - \frac{\bar{n}^{\mu}}{2}n \cdot D_n$. Since $\bar{n} \cdot p_n \gg 1$ the field $\Xi_n(x)$ has no pole in its propagator, similar to the field $H_v(x)$ in Eq. (16.3). It can therefore be integrated out using its equation of motion. Inserting this back into Eq. (16.15), we find

$$\mathcal{L}_{n} = \bar{\psi}_{n}(x) \left[i n \cdot D_{n} + i \not \!\! D_{n}^{\perp} \frac{1}{i \bar{n} \cdot D_{n}} i \not \!\! D_{n}^{\perp} \right] \frac{\vec{\eta}}{2} \psi_{n}(x). \tag{16.16}$$

While this Lagrangian leads to the correct Feynman rules of SCET, there is one feature that warrants extra discussion. In contrast to the Lagrangian of HQET given in Eq. (16.5), where the derivative scales like the residual momentum k of the heavy quark, the derivatives in Eq. (16.16) pick up both the large momentum components of order Q and $Q\lambda$, as well as the residual momentum of order $Q\lambda^2$. One can separate the large and residual momentum components using a procedure similar to the HQET case. Separating the collinear momentum into a "label" and a residual component, $p^{\mu} = P^{\mu} + k^{\mu}$, and performing a phase redefinition on the collinear fields $\psi_n(x) = e^{iP \cdot x} \xi_n(x)$, derivatives acting on the fields $\xi_n(x)$ now only pick out the residual momentum. Since the label momentum in SCET is not conserved as in HQET, one defines a label operator \mathcal{P}^{μ} acting as $\mathcal{P}^{\mu}\xi_n(x) = P^{\mu}\xi_n(x)$ [39], as well as a corresponding covariant label operator $i\mathcal{D}^{\mu}_n = \mathcal{P}^{\mu} + gA_n(x)$.

The final step to complete the Lagrangian of SCET is to include the interactions of collinear fields with soft fields. These interactions can be included by adding the soft gluons to the covariant derivatives, while preserving the power counting. This leads to the final SCET Lagrangian [39–41]

$$\mathcal{L}_{n} = \bar{\xi}_{n}(x) \left[in \cdot D_{n} + gn \cdot A_{s} + i \mathcal{P}_{n}^{\perp} \frac{1}{i\bar{n} \cdot \mathcal{D}_{n}} i \mathcal{P}_{n}^{\perp} \right] \frac{\vec{n}}{2} \xi_{n}(x). \quad (16.17)$$

The leading-order Lagrangian describing collinear fields in different light-like directions is simply given by the sum of the Lagrangians for each direction n separately, i.e. $\mathcal{L} = \sum_n \mathcal{L}_n$. The soft gluons are the same in each individual Lagrangian. An alternative way to understand the separation between large and small momentum components is to derive the Lagrangian of SCET in position space. In this case no label operators are required to describe interactions in SCET, and the dependence on short-distance effects is contained in non-localities at short distances. An important difference between SCET and HQET is that the SCET Lagrangian is not corrected by short distance fluctuations [42].

16.3.3. Collinear gauge invariance and Wilson lines: An important aspect of SCET is the gauge structure of the theory. Because the effective field operators in SCET describe modes with certain momentum scalings, the effective Lagrangian respects only residual gauge symmetries. One of them satisfies the collinear scaling

$$(\bar{n} \cdot \partial_n, n \cdot \partial_n, \partial_n^{\perp}) U_n(x) \sim Q(1, \lambda^2, \lambda) U_n(x),$$
 (16.18)

and one the soft scaling

$$(\bar{n} \cdot \partial_n, n \cdot \partial_n, \partial_n^{\perp}) U_s(x) \sim Q(\lambda^2, \lambda^2, \lambda^2) U_s(x).$$
 (16.19)

The fact that collinear fields in different directions do not transform under the same gauge transformations implies that each collinear sector, containing particles with large momenta along a certain direction, has to be separately gauge invariant. This is achieved by the introduction of collinear Wilson lines [39]

$$W_n(x) = P \exp\left[-ig \int_{-\infty}^0 ds \,\bar{n} \cdot A_n(s\bar{n} + x)\right],\tag{16.20}$$

which transform under collinear gauge transformations according to $W_n \to U_n W_n$. Thus, the combination $\chi_n \equiv W_n^\dagger \psi_n$ is gauge invariant. In a similar manner, one can define the gauge-invariant gluon field $B_n^\mu = g^{-1} W_n^\dagger i D_n^\mu W_n$ [43]. Operators in SCET are typically constructed from such gauge-invariant collinear fields.

16.3.4. Decoupling of soft gluons: Soft gluons in SCET couple to collinear quarks only through the term $\bar{\xi}_n gn \cdot A_s \frac{\vec{n}}{2} \xi_n$ in the effective Lagrangian in Eq. (16.17). This coupling is similar to the coupling of soft gluons to heavy quarks in HQET, and soft gluons in SCET can be decoupled from collinear fields in a way similar as explained in Section 16.2.4. Written in terms of the redefined fields

$$\psi_n(x) = Y_n(x)\psi_n^{(0)}(x), \qquad A_n(x) = Y_n(x)A_n^{(0)}(x)Y_n^{\dagger}(x), \quad (16.21)$$

the soft gluons decouple from the SCET Lagrangian [40]. This fact greatly facilitates proofs of factorization theorems in SCET.

16.3.5. Factorization Theorems: One of the important applications of SCET is to understand how to factorize cross sections involving energetic particles in different directions into simpler pieces that can either be calculated perturbatively or determined from data. Factorization theorems have been around for much longer than SCET. For a review on the subject, see [44]. However, the effective theory allows for a conceptually simpler understanding of certain classes of factorization theorems [45], since most simplifications happen already at the level of the Lagrangian. The discussion in this section is valid to leading order in the power counting of the effective theory.

As discussed in the previous section, the Lagrangian of SCET does not involve any couplings between collinear degrees of freedom in different light-like directions, or between soft and collinear degrees of freedom after the field redefinition Eq. (16.21) has been performed. An operator describing the scattering and production of collinear partons at short distances can thus be written as

$$\langle O(x) \rangle \simeq C_O(\mu) \times$$

$$\left\langle \mathcal{C}_{n_a}^{(0)}(x)\mathcal{C}_{n_b}^{(0)}(x)\mathcal{C}_{n_1}^{(0)}(x)\dots\mathcal{C}_{n_N}^{(0)}(x)[\mathcal{Y}_{n_a}\mathcal{Y}_{n_b}\mathcal{Y}_{n_1}\dots\mathcal{Y}_{n_N}](x)\right\rangle_{\mu}.$$
 (16.22)

Here $C_n(x)$ denotes a gauge-invariant combination of collinear fields (either quark or gluon fields) in the direction n, and the matching coefficient accounting for short-distance effects is denoted by C_O . The soft Wilson lines can either be in a color triplet or color octet representation, and are collectively denoted by \mathcal{Y}_n . Both the matrix elements and the coefficient C_O depend on the renormalization scale μ .

Having defined the operator mediating a given process, one can calculate the cross section by squaring the operator, taking the forward matrix element and integrating over the phase space of all final-state particles. The absence of interactions between collinear degrees of freedom moving along different directions or soft degrees of freedom implies that the forward matrix element of the operator can be factorized as

$$\left\langle \operatorname{in} \left| O(x) O^{\dagger}(0) \right| \operatorname{in} \right\rangle = \left\langle \operatorname{in}_{a} \left| \mathcal{C}_{n_{a}}(x) \mathcal{C}_{n_{a}}^{\dagger}(0) \right| \operatorname{in}_{a} \right\rangle \left\langle \operatorname{in}_{b} \left| \mathcal{C}_{n_{b}}(x) \mathcal{C}_{n_{b}}^{\dagger}(0) \right| \operatorname{in}_{b} \right\rangle$$

$$\times \left\langle 0 \left| \mathcal{C}_{n_{1}}(x) \mathcal{C}_{n_{1}}^{\dagger}(0) \right| 0 \right\rangle \cdots \left\langle 0 \left| \mathcal{C}_{n_{N}}(x) \mathcal{C}_{n_{N}}^{\dagger}(0) \right| 0 \right\rangle$$

$$\times \left\langle 0 \left| \left[\mathcal{Y}_{n_{a}} \dots \mathcal{Y}_{n_{N}} \right] (x) \left[\mathcal{Y}_{n_{a}} \dots \mathcal{Y}_{n_{N}} \right]^{\dagger} (0) \right| 0 \right\rangle.$$

$$\left\langle 0 \left| \left[\mathcal{C}_{n_{a}} \left(\mathcal{C}_{n_{a}} \right) \left(\mathcal{C}_{$$

Thus, the matrix element required for the differential cross section has factorized into a product of simpler structures, each of which can be evaluated separately.

For most applications the matrix elements of incoming collinear fields are non-perturbative objects given in terms of the well-known parton distribution functions, while the matrix elements of outgoing collinear fields are determined by perturbatively calculable jet functions $J_i(\mu)$. Finally, the vacuum matrix element of the soft Wilson lines defines a so-called soft function, commonly denoted by $S(\mu)$. The common dependence on x in the above equation implies that in momentum space the various components of the factorization theorem are convoluted with one another. Deriving this convolution requires a careful treatment of the phase-space integration, in particular treating the large and residual components of each momentum appropriately.

Putting all information together, the differential cross section can be written as

$$d\sigma \sim H(\mu) \otimes \left[f_{p_1/P}(\mu) f_{p_2/P}(\mu) \right] \otimes \left[J_1(\mu) \dots J_N(\mu) \right] \otimes S(\mu).$$
 (16.24)

The hard coefficient is equal to the square of the matching coefficient, $H(\mu) = |C_O(\mu)|^2$. It should be mentioned that the most difficult part of traditional factorization proofs involves showing that so-called Glauber gluons do not spoil the above factorization theorem. This question has not yet been fully addressed in the context of SCET.

16.3.6. Resummation of large logarithms: SCET can be used to sum the large logarithmic terms that arise in perturbative calculations. In general, perturbation theory will generate a logarithmic dependence on any ratio of scales r in a problem, and for processes that involve initial or final states with energy much in excess of their mass there are two powers of logarithms for every power of the strong coupling constant. Thus, for widely separated scales these large logarithms can spoil fixed-order perturbation theory, and a much better convergence is achieved by expanding in α_s , but holding $\alpha_s \log^2 r$ fixed, such that the first term in the new expansion resums powers of $\alpha_s \log^2 r$ to all orders. More precisely, a proper resummation requires to sum logarithms of the form $\alpha_s^n \log^m r$ with $m \leq n+1$ in the logarithm of a cross-section.

The important ingredient in achieving this resummation is the fact that SCET factorizes a given cross section into simpler pieces, as discussed in the previous section. Each of the ingredients of the factorization theorem depends on a single physical scale, and the only dependence on that scale can arise through logarithms of its ratio with the renormalization scale μ . Thus, for each of the components in the factorization theorem one can choose a renormalization scale μ for which the large logarithmic terms are absent.

Of course, the factorization formula requires a common renormalization scale μ in all its components, and one therefore has to use the RG to evolve the various component functions from their preferred

scale to the common scale μ . For example, for the hard coefficient $H(\mu)$, the RG equation can be written as

$$\mu \frac{\mathrm{d}}{\mathrm{d}\mu} H(\mu) = \gamma_H(\mu) H(\mu). \tag{16.25}$$

In general, the anomalous dimension is of the form $\gamma_H(\mu) = c_H \Gamma_{\rm cusp}(\alpha_s) \log(Q/\mu) + \gamma(\alpha_s)$, where c_H is a process-dependent coefficient and $\Gamma_{\rm cusp}$ denotes the so-called cusp anomalous dimension [18,46]. The non-cusp part of the anomalous dimension γ is again process dependent. The presence of a logarithm of the hard scale Q in the anomalous dimension is characteristic of Sudakov problems and arises since the perturbative series contains double logarithms of scale ratios. The anomalous dimension γ_H is known at two-loop order for arbitrary n-parton amplitudes containing massless or massive external partons [47–50]. Solving the RG equation yields

$$H(\mu) = U_H(\mu, \mu_h)H(\mu_h),$$
 (16.26)

which can be used to write the hard function at a scale $\mu_h \sim Q$, where its perturbative expression does not contain any large logarithms, in terms of the common renormalization scale μ . The RG evolution factor $U_H(\mu,\mu_h)$ sums logarithms of the form μ/μ_h . By calculating the anomalous dimension $\gamma_H(\mu)$ to higher and higher orders in perturbation theory, one can resum more and more logarithms in the evolution kernel. The RG equations for the jet and soft functions are more complicated, since they involve convolutions over the relevant momentum variables.

16.3.7. Applications: Most of the applications of SCET are either in flavor physics, where the decay of a heavy B meson can give rise to energetic light partons, or in collider physics, where the presence of jets naturally leads to collimated sets of energetic particles. For several of these applications alternative approaches existed before the invention of SCET, but the effective theory has opened up alternative ways to understand the physics of these processes. There are, however, many examples for which SCET has allowed new insights that were not available or possible without the effective theory. In particular, it has provided a field-theoretic basis for the QCD factorization approach to exclusive, non-leptonic decays of B mesons [51]. Using SCET methods, proofs of factorization were derived for the color-allowed decay $\bar{B}^0 \to D^+\pi^-$ [52], the color-suppressed decay $\bar{B}^0 \to D^0\pi^0$ [53], and the radiative decay $\bar{B} \to K^* \gamma$ [54]. Further examples are factorization theorems and the resummation of endpoint logarithms for quarkonia production [55], factorization theorems for cross sections defined through jet algorithms [56], the resummation of large logarithmic terms for the thrust [57] and jet broadening [58] distributions in e^+e^- annihilation beyond NLL order, the development of new factorizable observables to veto extra jets [59], all-orders factorization theorems for processes containing electroweak Sudakov logarithms [60], as well as the resummation of threshold (soft gluon) logarithms for several important processes at hadron colliders [61,62]. We describe two of these applications in more detail.

Event-shape distributions, in particular the thrust distribution, have been measured to high accuracy at LEP [63]. Comparing these data to precise theoretical predictions allows for a determination of the strong coupling constant α_s . For small values of $\tau \equiv 1-T$, the distribution can be factorized into the form [64,65]

$$\frac{1}{Q\sigma_0}\frac{\mathrm{d}\sigma}{\mathrm{d}\tau} = H(\mu)\int\mathrm{d}s\int\mathrm{d}k\,J(s,\mu)\,S(Q\tau-s/Q-k,\mu). \eqno(16.27)$$

Here Q denotes the center-of-mass energy of the collision, σ_0 is the total hadronic cross section, and $H,\ J$ and S are the hard, jet and soft functions in SCET. Large logarithms of the form $(\alpha_s^n \ln^{2n-1}\tau)/\tau$ become important and have to be resummed. Furthermore, for $\tau \sim \Lambda_{\rm QCD}/Q$ non-perturbative effects in the soft function become important. Using SCET the resummation of these large logarithms has been performed to N³LL, which is two orders beyond what was previously available [57]. The factorization in the effective theory has also allowed to include the non-perturbative physics through a shape function, very similar to the B-physics case discussed above.

The known perturbative effects for large values of τ can be included by matching the SCET result to the known two-loop spectrum [66,67]. Comparing the predicted to the measured thrust distribution allows for a precise determination of the strong coupling constant α_s [68].

For quarkonium produced in e^+e^- annihilation or photo-production, large logarithms arise in the region of phase space where the energy of the produced $Q\bar{Q}$ state is close to its maximum value. In this region the quarkonium is predominantly produced in a color-octet configuration and recoils against a collinear hadronic system. Then logarithms of the form $\log(1-E_{\Psi}/E_{\rm max})$ as well as non-perturbative effects become important and should be included in attempts to describe the data. While some of these issues had been addressed without the use of an effective theory (see [69] and references therein), a complete treatment of the endpoint region has only been achieved using SCET [55]. It was shown that including both effects consistently, theory and data can be brought into better agreement.

16.4. Open issues and perspectives

HQET has successfully passed many experimental tests, and there are not too many open questions that still need to be addressed. One issue that has not been derived from first principles is quark-hadron duality. The validity of global duality (at energies even lower than those relevant in B decays) has been tested experimentally using high-precision data on semileptonic B decays and on hadronic τ decays, and there has been good agreement between theory and data. However, assigning a theoretical uncertainty to possible duality violations is difficult. Another known issue is the that the measured value of the CKM element $|V_{cb}|$ is different depending of whether one uses inclusive or exclusive B decays to derive it (see the relevant section in the Particle Data Book). Both measurements rely on the heavy-quark limit, and the uncertainties quoted include the effects from power corrections arising from the finite b-quark mass.

SCET, on the other hand, is still an active field of research, and there are several open questions that need to be answered. In this review we have not discussed any issues having to do with SCET_{II}, which is the appropriate effective theory describing the interactions of collinear particles with soft particles having momentum scaling as $Q(\lambda,\lambda,\lambda)$. This is important, for example, to describe exclusive decays of B mesons into light, energetic mesons, or in collider-physics applications such as the p_T resummation for Drell-Yan production. There are still open issues in how to properly formulate SCET_{II}, which are under active investigation. They include the treatment of endpoint singularities of convolution integrals, double counting between overlapping momentum regions, and the breakdown of the naive factorization of soft and collinear modes due to quantum effects. Glauber gluons are known to affect factorization theorems, but how to properly include them in SCET is still an open question.

17. LATTICE QUANTUM CHROMODYNAMICS

Written September 2011 by S. Hashimoto (KEK), J. Laiho (University of Glasgow) and S.R. Sharpe (University of Washington).

17.1. Lattice regularization of QCD

Gauge theories form the building blocks of the Standard Model. While the SU(2) and U(1) parts have weak couplings and can be studied accurately with perturbative methods, the SU(3) component-QCD—is only amenable to a perturbative treatment at high energies. The growth of the coupling constant in the infrared—the flip-side of asymptotic freedom—requires the use of non-perturbative methods to determine the low energy properties of QCD. Lattice gauge theory, proposed by K. Wilson in 1974 [1], provides such a method, for it gives a non-perturbative definition of vector-like gauge field theories like QCD. In lattice regularized QCD—commonly called lattice QCD or LQCD—Euclidean space-time is discretized, usually on a hypercubic lattice with lattice spacing a, with quark fields placed on sites and gauge fields on the links between sites. The lattice spacing plays the role of the ultraviolet regulator, rendering the quantum field theory finite. The continuum theory is recovered by taking the limit of vanishing lattice spacing, which can be reached by tuning the bare coupling constant to zero according to the renormalization group.

Unlike dimensional regularization, which is commonly used in continuum QCD calculations, the definition of LQCD does not rely on the perturbative expansion. Indeed, LQCD allows non-perturbative calculations by numerical evaluation of the path integral that defines the theory.

Practical LQCD calculations are limited by the availability of computational resources and the efficiency of algorithms. Because of this, LQCD results come with both statistical and systematic errors, the former arising from the use of Monte-Carlo integration, the latter, for example, from the use of non-zero values of a. There are also different ways in which the QCD action can be discretized, and all must give consistent results in the continuum limit. It is the purpose of this review to provide an outline of the methods of LQCD, with particular focus on applications to particle physics, and an overview of the various sources of error. This should allow the reader to better understand the LQCD results that are presented in other sections for a variety of quantities (quark masses, the hadron spectrum and several electroweak matrix elements). For more extensive explanations the reader should consult the available text books, the most up-to-date of which are Refs. [2,3,4].

17.1.1. Gauge invariance, gluon fields and the gluon action:

A key feature of the lattice formulation of QCD is that it preserves gauge invariance. This is in contrast to perturbative calculations, where gauge fixing is an essential step. The preservation of gauge invariance leads to considerable simplifications, e.g. restricting the form of operators that can mix under renormalization.

The gauge transformations of lattice quark fields are just as in the continuum: $q(x) \longrightarrow V(x)q(x)$ and $\bar{q}(x) \longrightarrow \bar{q}(x)V^{\dagger}(x)$, with V(x) an arbitrary element of SU(3). The only difference is that the Euclidean space-time positions x are restricted to lie on the sites of the lattice, i.e. $x = a(n_1, n_2, n_3, n_4)$ for a hypercubic lattice, with the n_i being integers. Quark bilinears involving different lattice points can be made gauge invariant by introducing the gluon field $U_{\mu}(x)$. For example, for adjacent points the bilinear is $\bar{q}(x)U_{\mu}(x)q(x+a\hat{\mu})$, with $\hat{\mu}$ the unit vector in the μ 'th direction. (This form is used in the construction of the lattice covariant derivative.) The gluon field (or "gauge link") is an element of the group, SU(3), in contrast to the continuum field A_{μ} which takes values in the Lie algebra. The bilinear is invariant if U_{μ} transforms as $U_{\mu}(x) \to V(x)U_{\mu}(x)V^{\dagger}(x+a\hat{\mu})$. The lattice gluon field is naturally associated with the link joining x and $x+a\hat{\mu}$, and corresponds in the continuum to a Wilson line connecting these two points, $P \exp(i \int_x^{x+a\hat{\mu}} dx_{\mu} A_{\mu}^{\rm cont}(x))$ (where P indicates a path-ordered integral, and the superscript on A_{μ} indicates that it is a continuum field). The trace of a product of the $U_{\mu}(x)$ around any closed loop is easily seen to be gauge invariant and is the lattice version of a Wilson

The simplest possible gauge action, usually called the Wilson gauge action, is given by the product of gauge links around elementary

plaquettes:

$$S_g = \beta \sum_{x,\mu\nu} [1 - \text{ReTr}[U_{\mu}(x)U_{\nu}(x+a\hat{\mu})U_{\mu}^{\dagger}(x+a\hat{\nu})U_{\nu}^{\dagger}(x)]/3]. \quad (17.1)$$

For small a, assuming that the fields are slowly varying, one can expand the action in powers of a using $U_{\mu}(x) = \exp(iaA_{\mu}(x))$. Keeping only the leading non-vanishing term, and replacing the sum with an integral, one finds the continuum form,

$$S_g \longrightarrow \int d^4x \frac{1}{4g_{\rm lat}^2} \text{Tr}[F_{\mu\nu}^2(x)], \qquad (F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu])$$

$$(17.2)$$

as long as one chooses $\beta=6/g_{\rm lat}^2$ for the lattice coupling. In this expression, $g_{\rm lat}$ is the bare coupling constant in the lattice scheme, which can be related (by combining continuum and lattice perturbation theory) to a more conventional coupling constant such as that in the $\overline{\rm MS}$ scheme (see Sec. 17.3.4 below).

In practice, the lattice spacing a is non-zero, leading to discretization errors. In particular, the lattice breaks Euclidean rotational invariance (which is the Euclidean version of Lorentz invariance) down to a discrete hypercubic subgroup. One wants to reduce discretization errors as much as possible. A very useful tool in this regard is the Symanzik effective action: the interactions of quarks and gluons with momenta low compared to the lattice cutoff ($|p| \ll 1/a$) are described by a continuum action consisting of the standard continuum terms (e.g. the gauge action given in Eq. (17.2)) augmented by higher dimensional operators suppressed by powers of a [5]. For the Wilson lattice gauge action, the leading correction comes in at $\mathcal{O}(a^2).$ It takes the form $\sum_j a^2 O_6^{(j)},$ with the sum running over all dimension-six operators $O_6^{(j)}$ allowed by the *lattice* symmetries. Some of these operators violate Euclidean invariance, and all of them lead to discretization errors proportional to a^2 . These errors can, however, be reduced by adding corresponding operators to the lattice action and tuning their coefficients to eliminate the dimension-six operators in the effective action to a given order in perturbation theory. This is the idea of the Symanzik improvement program [5]. In the case of the gauge action, one adds loops involving six gauge links (as opposed to the four links needed for the original plaquette action, Eq. (17.1) to define the $\mathcal{O}(a^2)$ improved (or "Symanzik") action [6]. In practical implementations, the improvement is either at tree-level (so that residual errors are proportional to $\alpha_s a^2$, where the coupling is evaluated at a scale $\sim 1/a$), or at one loop order (errors proportional to $\alpha_s^2 a^2$). Another popular choice is motivated by studies of renormalization group (RG) flow. It has the same terms as the $\mathcal{O}(a^2)$ improved action but with different coefficients, and is called the RG-improved or "Iwasaki" action [7].

17.1.2. Lattice fermions:

Naive discretization of the continuum fermion action $S_f=\int d^4x \bar{q}[i\partial_\mu\gamma_\mu+m]q$, in which one replaces the derivative $\partial_\mu q$ by a discrete difference $[q(x+a\hat{\mu})-q(x-a\hat{\mu})]/2a$, leads to the fermion doubling problem—the resulting action describes 2^d equivalent fermion fields in the continuum limit in d dimensions. The appearance of the extra "doubler" fermions is related to the deeper theoretical problem of formulating chirally symmetric fermions on the lattice. This is encapsulated by the Nielsen-Ninomiya theorem [8]: one cannot define lattice fermions having exact, continuum-like chiral symmetry without producing doublers. Naive lattice fermions do have chiral symmetry but at the cost of introducing 15 unwanted doublers (for d=4).

The doubling problem has been addressed in various ways, each coming with different pros and cons. Wilson fermions [1] add a term proportional to $a\bar{q}\Delta q$ to the fermion action (the "Wilson term"—in which Δ is a covariant lattice Laplacian). This gives a mass of $\mathcal{O}(1/a)$ to the doublers, so that they decouple in the continuum limit. The Wilson term, however, violates chiral symmetry, and also introduces discretization errors linear in a. A commonly used variant that eliminates the $\mathcal{O}(a)$ discretization error is the $\mathcal{O}(a)$ -improved Wilson (or "clover") fermion [9]. In this application of Symanzik improvement, methods have been developed to remove $\mathcal{O}(a)$ terms to all orders in perturbation theory using auxiliary simulations to tune parameters ("non-perturbative improvement") [10].

The advantages of Wilson fermions are their theoretical simplicity and relatively small computational cost. The disadvantage is their lack of chiral symmetry, which makes them difficult to use in cases where mixing with wrong chirality operators can occur, particularly if this involves divergences proportional to powers of 1/a. A related problem is potential numerical instabilities due to spurious near-zero modes. Ongoing work has, however, been successful at ameliorating these problems and increasing the range of quantities for which Wilson fermions can be used.

Twisted-mass fermions [11] are a variant of Wilson fermions which remove the numerical instability problem by treating two flavors of fermions together and adding an isospin-breaking mass term (the "twisted mass" term). Another advantage of this approach is that all errors linear in a are automatically removed (without the need for tuning of parameters) by a clever choice of twisted mass and operators.

Staggered fermions are a reduced version of naive fermions in which there is only a single fermion Dirac component on each lattice site, with the full Dirac structure built up from neighboring sites [12]. They have the advantages of being somewhat faster to simulate than Wilson-like fermions, of preserving some chiral symmetry, and of having discretization errors of $\mathcal{O}(a^2)$. Their disadvantage is that they retain some of the doublers (3 for d=4). The action thus describes four degenerate fermions in the continuum limit. The resulting SU(4) flavor symmetry is usually called "taste symmetry", and the preserved chiral symmetry in this formulation has non-singlet taste. Practical applications usually introduce one staggered fermion for each physical flavor, and remove contributions from the unwanted tastes by taking the fourth-root of the fermion determinant appearing in the path integral. The validity of this "rooting" procedure is not obvious because taste symmetry is violated for non-zero lattice spacing. Theoretical arguments, supported by numerical evidence, suggest that the procedure is valid as long as one takes the continuum limit before approaching the light quark mass region [13].

Just as for Wilson fermions, the staggered action can be improved, so as to reduce discretization errors. The widely used "asqtad" action [14] removes tree-level $\mathcal{O}(a^2)$ errors, and leads to substantial reduction in the breaking of taste symmetry. More recently, a highly improved staggered quark ("HISQ") action has been introduced [15], which further reduces taste symmetry-breaking and can also be used for heavy quarks such as charm.

There is an important class of lattice fermions that possess a continuum-like chiral symmetry without introducing unwanted doublers. The Dirac operator D for these fermions satisfies the Ginsparg-Wilson relation $D\gamma_5 + \gamma_5 D = aD\gamma_5 D$ [16]. In the continuum, the right-hand-side vanishes due to chiral symmetry. On the lattice, it is non-vanishing, but with a particular form (with two factors of D) that restricts the violations of chiral symmetry in Ward-Takahashi identities to short-distance terms that do not contribute to physical matrix elements. In fact, one can define a modified chiral transformation on the lattice (by including dependence on the gauge fields) such that "Ginsparg-Wilson fermions" have an exact chiral symmetry [17]. The net result is that such fermions essentially have the same properties under chiral transformations as do continuum fermions. Their leading discretization errors are of $\mathcal{O}(a^2)$.

Two types of Ginsparg-Wilson fermions are being used in large-scale projects. The first are Domain-wall fermions (DWF). These are defined on a five-dimensional space, in which the fifth dimension is fictitious [18]. The action is chosen so that the low-lying modes are chiral, with left- and right-handed modes localized on opposite four-dimensional surfaces. For an infinite fifth dimension, these fermions satisfy the Ginsparg-Wilson relation. In practice, the fifth dimension is kept finite, and there remains a small, controllable violation of chiral symmetry. The second type are Overlap fermions. These appeared from a completely different context and have an explicit form that exactly satisfies the Ginsparg-Wilson relation [19]. Their numerical implementation requires an approximation of the matrix sign function of a Wilson-like fermion operator, which is costly, instead of treating five-dimensional fields in the case of DWF.

As noted above, each fermion formulation has its own advantages and disadvantages. For instance, domain-wall and overlap fermions are

theoretically preferred as they have chiral symmetry without doublers, but their computational cost is at least an order of magnitude greater than for other choices. If the physics application of interest does not require near-exact chiral symmetry, there is no strong motivation to use these expensive formulations. On the other hand, there is a class of applications (including the calculation of the $\Delta I=1/2$ amplitude for $K\to\pi\pi$ decays and the S-parameter [20]) where chiral symmetry plays an essential role and for which the use of Ginsparg-Wilson fermions is strongly favored.

17.1.3. Heavy quarks on the lattice:

The fermion formulations described in the previous subsection are useful only for quarks whose masses are small compared to the lattice cutoff, $m \lesssim 1/a$. This is because there are discretization errors proportional to powers of am, and if $am \gtrsim 1$ these errors are large and uncontrolled. Present LQCD simulations typically have cutoffs in the range of 1/a = 2-4 GeV (corresponding to $a \approx 0.1-0.05$ fm), so that bottom quarks (with $m_b \approx 4.5$ GeV) require alternative discretizations while charm quarks ($m_c \approx 1.5$ GeV) are a borderline case.

For the charm quark, a straightforward approach is to simultaneously reduce the lattice spacing and to improve the fermion action so as to reduce the size of errors proportional to powers of am_c . This approach has, for example, been followed successfully by the HPQCD collaboration using the HISQ action [15]. It is important to note, however, that reducing a increases the computational cost because an increased number of lattice points are needed for the same physical volume. One cannot reduce the spatial size below 2-3 fm without introducing finite volume errors. Present lattices have sizes up to $\sim 64^3 \times 144$ (with the long direction being Euclidean time), and thus allow a lattice cutoff up to $1/a \sim 4$ GeV.

Other choices for the heavy quark action are motivated by effective field theories. For a bottom quark in heavy-light hadrons, one can use Heavy Quark Effective Theory (HQET) to expand about the infinite quark-mass limit, in which the bottom quark is a static color source [21]. Corrections, proportional to powers of $1/m_b$, can be introduced as operator insertions, with coefficients that can be determined non-perturbatively using existing techniques [22].

Another way of introducing the $1/m_b$ corrections is to include the relevant terms in the effective action. This leads to a non-relativistic QCD (NRQCD) action, in which the heavy quark is described by a two-component spinor [23]. This approach has the advantage over HQET that it can also be used for heavy-heavy systems, such as the Upsilon states. A disadvantage is that some of the parameters in this effective theory are determined perturbatively (in practice at tree-level, or in some cases at one-loop), which limits the precision of the final results. Although discretization effects can be controlled within NRQCD, at fine enough lattice spacings the NRQCD effective theory no longer applies since power divergent terms become important, and taking the continuum limit would require fine-tuning a large number of couplings non-perturbatively.

This problem can be avoided if one uses HQET power counting to reduce heavy-quark discretization effects. This can be accomplished by tuning the parameters of an improved Wilson quark action so that the leading HQET corrections to the static quark limit are correctly accounted for. As the lattice spacing becomes finer, the action smoothly goes over to that of a light Wilson quark action, where the continuum limit can be taken as usual. In principle, one can improve the action in the heavy quark regime up to arbitrarily high orders using HQET, but so far large-scale simulations have typically used clover improved Wilson quarks, where tuning the parameters of the action corresponds to including all corrections through next-to-leading order in HQET. Three different methods for tuning the parameters of the clover action are being used: the Fermilab [24], Tsukuba [25] and Columbia [26] approaches. An advantage of this HQET approach is that the c and b quarks can be treated on the same footing. On the other hand, as in NRQCD the tuning of the parameters in the effective action is typically done perturbatively, though a first attempt to tune them non-perturbatively has been made [27].

17.1.4. Basic inputs for lattice calculations:

Since LQCD is a regularization of QCD, the number of input parameters is the same as for continuum QCD—the strong coupling constant $\alpha_s = g^2/(4\pi)$, the quark masses for each flavor, and the CP violating phase θ . The θ parameter is usually assumed to be zero, while the other parameters must be determined using experimental inputs.

17.1.4.1. Lattice spacing: In QCD, the coupling constant is a function of scale. With lattice regularization, this scale is the inverse lattice spacing 1/a, and choosing the bare coupling constant is equivalent to fixing the lattice spacing.

In principle, a can be determined using any dimensionful quantity measured by experiments. For example, using the mass of hadron H one has $a=(am_H)^{\rm lat}/m_H^{\rm exp}$. (Of course, one must first tune the quark masses to their physical values, as discussed below.) In practice, one chooses quantities that can be calculated accurately on the lattice, and that are only weakly dependent on the light quark masses. The latter property minimizes errors from extrapolating to the physical light quark masses or from mistuning of these masses. Two commonly used choices are the spin-averaged 1S-1P or 1S-2S splittings in the Upsilon system, and the mass of the Ω^- baryon. The former has the advantage that it is insensitive to the b-quark mass, but the disadvantage that it requires a discretized heavy quark action.

The determination of a using quantities involving light (up and down) quarks—such as the nucleon mass or the pion decay constant—is more challenging. Most current lattice simulations are done using light quark masses heavier than those in nature. One thus has to extrapolate the lattice data towards the physical quark masses. This "chiral extrapolation" is non-trivial because the quark mass dependence may involve non-analytic terms due to the loops of nearly massless pions, as predicted by Chiral Perturbation Theory (ChPT) [28].

17.1.4.2. Light quark masses: In LQCD simulations, the up, down and strange quarks are usually referred to as the light quarks, in the sense that $m_q < \Lambda_{\rm QCD}$. (The standard definition of $\Lambda_{\rm QCD}$ is given in the "Quantum Chromodynamics" review; in this review we are using it only to indicate the approximate non-perturbative scale of QCD.) This condition is stronger than that used above to distinguish quarks with small discretization errors, $m_q < 1/a$. Loop effects from light quarks must be included in the simulations to accurately represent QCD. At present, most simulations are done in the isospin symmetric limit $m_u = m_d \equiv m_\ell$, and are often referred to as " $N_f = 2 + 1$ " simulations. Precision is now reaching the point where isospin breaking effects, as well as those of electromagnetism (EM) must be included. This can be done approximately using ChPT and other theoretical input, but ultimately one needs to simulate directly with $m_u \neq m_d$ and including QED corrections. Such work is now beginning.

To tune m_ℓ and m_s to their physical values, the most commonly used quantities are, respectively, m_π and m_K . If the scale is being set by m_Ω , then one adjusts the lattice light quark masses until the ratios m_π/m_Ω and m_K/m_Ω take their physical values. At leading order in ChPT, one has the Gell-Mann-Oakes-Renner relations $m_{\pi^0}^2 \propto (m_u + m_d)$ and $m_K^2 \propto (m_d + m_s)$, which shows the sensitivity of these quantities to the quark masses. In practice one uses higher order ChPT (or other fit functions) to extrapolate or interpolate the lattice results so as to match the desired ratios, correcting for the (small) effects of isospin breaking and electromagnetic corrections. Most present calculations need to extrapolate to the physical value of m_ℓ , while simulating directly at or near to the physical value of m_s .

17.1.4.3. Heavy quark masses: Heavy quarks (c and b) are usually treated only as valence quarks, with no loop effects included. Generically, the errors introduced by this approximation are $\sim \alpha_s(m_c) \Lambda_{\rm QCD}^2/m_c^2$ and are small. For high precision, however, dynamical charm quarks may be necessary, and simulations are beginning to include them.

The heavy quark masses can be tuned by setting heavy-heavy or heavy-light meson masses to their experimental values. For the charm quark, for example, one could use the J/ψ or the D_s meson.

Consistency between these two determinations provides an important check on the lattice formulation used for the heavy quark [29].

17.1.5. Sources of systematic error:

Lattice results have statistical and systematic errors that must be quantified for any calculation in order for the result to be a useful input to phenomenology. The statistical error is due to the use of Monte Carlo importance sampling to evaluate the path integral (a method discussed below) and is the most straightforward error to estimate. There are, in addition, a number of systematic errors that are always present to some degree in lattice calculations, although the size of any given error depends on the particular quantity under consideration and the parameters of the lattices being used. The most common lattice errors are reviewed below.

17.1.5.1. Continuum limit: Physical results are obtained in the limit that the lattice spacing a goes to zero. The Symanzik effective theory determines the scaling of lattice errors with a. Most lattice calculations use improved actions with leading discretizations errors of $\mathcal{O}(a^2\Lambda^2)$ or $\mathcal{O}(\alpha_s a\Lambda)$, where Λ is a typical momentum scale in the system. Knowledge of the scaling of the leading discretization errors allows controlled extrapolation to a=0 when multiple lattice spacings are available, as in current state-of-the-art calculations. Residual errors arise from the exclusion of subleading a dependence from the fits

For many quantities the typical momentum scale in the system is $\sim \Lambda_{\rm QCD} \approx 300$ MeV. Discretization errors are expected to be larger for quantities involving larger scales, for example form factors or decays involving particles with momenta larger than $\Lambda_{\rm QCD}$.

17.1.5.2. Infinite volume limit: LQCD calculations are necessarily carried out in finite space-time boxes, leading to departures of physical quantities (masses, decay constants, etc.) from their measured, infinite volume values. These finite-volume shifts are an important systematic that must be estimated and minimized.

Typical lattices are asymmetric, with N_s points in the three spatial directions and N_t in the (Euclidean) temporal direction. The spatial and temporal sizes in physical units are thus $L_s = aN_s$ and $L_t = aN_t$, respectively. (Anisotropic lattice spacings are also sometimes used, as discussed below in Sec. 17.3.1.) Typically, $L_t \geq 2L_s$, so that the dominant impact of using finite volume is from the presence of a finite spatial box.

At present, high-precision LQCD calculations are of quantities involving no more than a single particle in initial and final states. For such quantities, once the volume exceeds about 2 fm (so that the particle is not "squeezed"), the dominant finite-volume effect comes from virtual pions wrapping around the lattice in the spatial directions. This effect is exponentially suppressed as the volume becomes large, roughly as $\sim \exp(-m_\pi L_s)$, and has been estimated using ChPT [30] or other methods [31]. The estimates suggest that finite volume shifts are sub-percent effects when $m_\pi L_s \gtrsim 4$, and most large-scale simulations use lattices satisfying this condition. This becomes challenging as one approaches the physical pion mass, for which $L_s \gtrsim 5$ fm is required. At present, this can only be achieved by using relatively coarse lattices, $a \gtrsim 0.07$ fm.

Finite volume errors are usually determined by repeating the simulations on two or more different volumes (with other parameters fixed). If different volumes are not available, the ChPT estimate can be used, often inflated to account for the fact that the ChPT calculation is truncated at some order.

In the future, LQCD calculations involving more than a single hadron will become increasingly precise. Examples include the calculation of resonance parameters and $K \to \pi\pi$ amplitudes. Finite volume effects are much larger in these cases, with power-law terms (e.g. $1/L_s^3$) in addition to exponential dependence. Indeed, as will be discussed in Sec. 17.2.4, one can use the volume dependence to indirectly extract infinite-volume quantities such as scattering lengths. Doing so, however, requires a set of lattice volumes satisfying $m_\pi L_s \gtrsim 4$ and is thus more challenging than for single-particle quantities.

17.1.5.3. Chiral extrapolation: An important source of systematic error in most LQCD calculations is the need to extrapolate in m_u and m_d (or, equivalently, in m_π). To do this, one needs a functional form that is, at least approximately, valid for pion masses ranging from the unphysical values used in simulations down to the physical value. A theoretically favored choice is to use the predictions of SU(3) or SU(2) ChPT. This is a valid description of QCD for $m_q \ll \Lambda_{QCD}$ (or $m_\pi \ll m_\rho$), but it is not known a priori the extent to which it applies at larger pion masses. This concern is exacerbated in practice since one must truncate the ChPT expressions, typically at one-loop or two-loop order. Experience to date suggests that one-loop expressions are not sufficiently accurate if $m_\pi \gtrsim 400$ MeV [32].

Another choice of fit function is based on the observation that one does not need to extrapolate to the chiral limit, but only to the physical, non-zero, value of m_{π} , and thus an analytic description might suffice. In practice, of course, one must truncate the analytic form at low order, and a concern is whether the curvature from known non-analytic terms is adequately reproduced.

In either approach, extrapolation errors are estimated by varying the fit function and the number of data points included. We also note that, in many calculations, additional input to the chiral extrapolation is obtained from "partially quenched" results in which the valence and sea-quark masses differ [33].

Very recently, simulations with physical light quark masses (except that $m_u = m_d = (m_u^{\rm phys} + m_d^{\rm phys})/2$) have been undertaken [34]. This is a major step forward as it removes the need for chiral extrapolation. As noted above, such simulations require large boxes, and thus very large lattices, and to date the results have been used to compute a limited number of observables. In the future, however, such simulations will play an increasingly important role in the determination of physical quantities.

17.1.5.4. Operator matching: Many of the quantities that LQCD can calculate precisely involve hadronic matrix elements of operators from the electroweak Hamiltonian. Examples include the pion and kaon decay constants, semileptonic form factors and the kaon mixing parameter B_K (the latter defined in Eq. (17.12)). The operators in the lattice matrix elements are defined in the lattice regularization scheme. To be used in tests of the Standard Model, however, they must be matched to the continuum regularization scheme in which the corresponding Wilson coefficients have been calculated. The only case in which such matching is not needed is if the operator is a conserved or partially conserved current. Similar matching is also needed for the conversion of lattice bare quark masses to those in the continuum $\overline{\rm MS}$ scheme.

Three methods are used to calculate the matching factors: perturbation theory (usually to one- or two-loop order), non-perturbative renormalization (NPR) using Landau-gauge quark and gluon propagators [35], and NPR using gauge-invariant methods based on the Schrödinger functional [36]. The NPR methods replace truncation errors (which can only be approximately estimated) by statistical and systematic errors which can be determined reliably and systematically reduced.

A common issue that arises in many such calculations (e.g. for quark masses and B_K) is that, using NPR, one ends up with operators regularized in a MOM-like (or Schrödinger functional) scheme, rather than the $\overline{\rm MS}$ scheme mostly used for calculating the Wilson coefficients. To make contact with this scheme requires a purely continuum perturbative matching calculation. The resultant truncation error can, however, be minimized by pushing up the momentum scale at which the matching is done using step-scaling techniques as part of the NPR calculation [37]. It should also be noted that this final step in the conversion to the $\overline{\rm MS}$ scheme could be avoided if continuum calculations used a MOM-like scheme.

17.2. Methods and status

Once the lattice action is chosen, it is straightforward to define the quantum theory using the path integral formulation. The Euclidean-space partition function is

$$Z = \int [dU] \prod_{f} [dq_f] [d\bar{q}_f] e^{-S_g[U] - \sum_{f} \bar{q}_f(D[U] + m_f) q_f}, \qquad (17.3)$$

where link variables are integrated over the SU(3) manifold, q_f and \bar{q}_f are Grassmann (anticommuting) quark and antiquark fields of flavor f, and D[U] is the chosen lattice Dirac operator with m_f the quark mass in lattice units. Integrating out the quark and antiquark fields, one arrives at a form suitable for simulation:

$$Z = \int [dU]e^{-S_g[U]} \prod_f \det(D[U] + m_f).$$
 (17.4)

The building blocks for calculations are expectation values of multi-local gauge-invariant operators,

$$\mathcal{O}(U,q,\bar{q})\rangle =$$

$$(1/Z)\int [dU]\prod_{f}[dq_{f}][d\bar{q}_{f}]\mathcal{O}(U,q,\bar{q})e^{-S_{g}[U]-\sum_{f}\bar{q}_{f}(D[U]+m_{f})q_{f}}.$$

$$(17.5)$$

If the operators depend on the (anti-)quark fields q_f and \bar{q}_f , then integrating these fields out leads not only to the fermion determinant but also, through Wick's theorem, a series of quark "propagators", $(D[U]+m_f)^{-1}$, connecting the positions of the fields.

17.2.1. Monte-Carlo method:

Since the number of integration variables U is huge $(N_s^3 \times N_t \times 4 \times 9)$, direct numerical integration is impractical and one has to use Monte-Carlo techniques. In this method, one generates a Markov chain of gauge configurations (a "configuration" being the set of U's on all links) distributed according to the probability measure $[dU]e^{-S_g[U]}\prod_f \det(D[U]+m_f)$. Once the configurations are generated, expectation values $\langle \mathcal{O}(U,q,\bar{q})\rangle$ are calculated by averaging over those configurations. In this way the configurations can be used repeatedly for many different calculations, and there are several large collections of ensembles of configurations (with a range of values of a, lattice sizes and quark masses) that are generally available. As the number of the configurations, N, is increased, the error decreases as $1/\sqrt{N}$, as long as the configurations are statistically independent.

The most challenging part of the generation of gauge configurations is the need to include the fermion determinant. Direct evaluation of the determinant is not feasible, as it requires $\mathcal{O}((N_s^3 \times N_t)^3)$ computations. Instead, one rewrites it in terms of "pseudofermion" fields ϕ (auxiliary fermion fields with bosonic statistics). For example, for two degenerate quarks one has

$$\det(D[U] + m_f)^2 = \int [d\phi] e^{-\phi^{\dagger}(D[U] + m_f)^{-2}\phi}.$$
 (17.6)

By treating the pseudofermions as additional integration variables in the path integral, one obtains a totally bosonic representation. The price one pays is that the pseudofermion effective action is highly non-local since it includes the inverse Dirac operator $(D[U]+m_f)^{-1}$. Thus, the large sparse matrix (D[U]+m) has to be inverted every time one needs an evaluation of the effective action.

Present simulations generate gauge configurations using the Hybrid Monte Carlo (HMC) algorithm [38], or variants thereof. This algorithm combines molecular dynamics (MD) evolution in a fictitious time (which is also discretized) with a Metropolis "accept-reject" step. It makes a global update of the configuration, and is made exact by the Metropolis step. In its original form it can be used only for two degenerate flavors, but extensions (particularly the rational HMC [39]) are available for single flavors. Considerable speed-up of the algorithms has been achieved over the last two decades using a variety of techniques.

All these algorithms spend the bulk of their computational time on the repeated inversion of (D[U] + m) acting on a source (which

is required at every step of the MD evolution). Inversions are done using iterative algorithms such as the conjugate gradient algorithm and its generalizations. In this class of algorithms, computational cost is proportional to the condition number of the matrix, which is the ratio of maximum and minimum eigenvalues. For (D[U]+m) the smallest eigenvalue is $\approx m$, so the condition number and cost are inversely proportional to the quark mass. This is a major reason why simulations at the physical quark mass are challenging. Recent algorithmic improvements, however, promise to significantly reduce or remove this problem.

A practical concern is the inevitable presence of correlations between configurations in the Markov chain. These are characterized by an autocorrelation length in the fictitious MD time. One aims to use configurations separated in MD time by greater than this autocorrelation length. In practice, it is difficult to measure this length accurately, and this leads to some uncertainty in the resulting statistical errors.

For most of the applications of LQCD discussed in this review, the cost of generating gauge configurations is larger than that of performing the "measurements" on those configurations. The computational cost of the HMC and related algorithms grows with the lattice volume, $V_{\rm lat} = N_s^3 N_t$, as $V_{\rm lat}^{5/4}$ [40]. This provides a (time-dependent) limit on the largest lattice volumes that can be simulated. At present, the largest lattices being used have $N_s = 64$ and $N_t = 144$. Typically one aims to create an ensemble of $\sim 10^3$ statistically independent configurations at each choice of parameters $(a, m_q \text{ and } V_{\rm lat})$. For most physical quantities of interest, this is sufficient to make the resulting statistical errors smaller than or comparable to the systematic errors.

17.2.2. Two-point functions:

One can extract properties of stable hadrons using two-point correlation functions, $\langle O_X(x)O_Y^{\dagger}(0)\rangle$. Here $O_{X,Y}(x)$ are operators that have non-zero overlaps with the hadronic state of interest $|H\rangle$, i.e. $\langle 0|O_{X,Y}(x)|H\rangle \neq 0$. One usually Fourier-transforms in the spatial directions and considers correlators as a function of Euclidean time:

$$C_{XY}(t;\vec{p}) = \sum_{\vec{x}} \langle O_X(t,\vec{x}) O_Y^{\dagger}(0) \rangle e^{-i\vec{p}\cdot\vec{x}}. \tag{17.7}$$

(Here and throughout this section all quantities are expressed in dimensionless lattice units, so that, for example, $\vec{p}=a\vec{p}_{\rm phys}$.) By inserting a complete set of states having spatial momentum \vec{p} , the two-point function can be written as

$$C_{XY}(t;\vec{p}) = \sum_{i=0}^{\infty} \frac{1}{2E_i(\vec{p})} \langle 0|O_X(0)|H_i(\vec{p})\rangle \langle H_i(\vec{p})|O_Y^{\dagger}(0)|0\rangle e^{-E_i(\vec{p})t},$$
(17)

where the energy of the *i*-th state $E_i(\vec{p})$ appears as an eigenvalue of the time evolution operator e^{-Ht} in the Euclidean time direction. The factor of $1/[2E_i(\vec{p})]$ is due to the relativistic normalization used for the states. For large enough t, the dominant contribution is that of the lowest energy state $|H_0(\vec{p})\rangle$:

$$C_{XY}(t) \overset{t \to \infty}{\longrightarrow} \frac{1}{2E_0(\vec{p})} \langle 0|O_X(0)|H_0(\vec{p})\rangle \langle H_0(\vec{p})|O_Y^\dagger(0)|0\rangle e^{-E_0(\vec{p})t} \ . \ \ (17.9)$$

One can thus obtain the energy $E_0(\vec{p})$, which equals the hadron mass m_H when $\vec{p} = 0$, and the product of matrix elements $\langle 0|O_X(0)|H_i(\vec{p})\rangle\langle H_i(\vec{p})|O_Y^\dagger(0)|0\rangle$.

This method can be used to determine the masses of all the stable mesons and baryons by making appropriate choices of operators. For example, if one uses the axial current, $O_X = O_Y = A_\mu = \bar{d}\gamma_\mu\gamma_5 u$, then one can determine m_{π^+} from the rate of exponential fall-off, and in addition the decay constant f_π from the coefficient of the exponential. A complication arises for states with high spins $(j \geq 4 \text{ for bosons})$ because the spatial rotation group on the lattice is a discrete subgroup of the continuum group SO(3). This implies that lattice operators, even when chosen to lie in irreducible representations of the lattice rotation group, have overlap with states that have a number of values of j in the continuum limit [41]. For example j=0 operators can

also create mesons with j = 4. A method to overcome this problem has recently been introduced [42].

The expression given above for the correlator $C_{XY}(t;\vec{p})$ shows how, in principle, one can determine the energies of the excited hadron states having the same quantum numbers as the operators $O_{X,Y}$, by fitting the correlation function to a sum of exponentials. In practice, this usually requires using a large basis of operators and adopting the variational approach such as that of Ref. [43]. One can also use an anisotropic lattice in which a_t , the lattice spacing in the time direction, is smaller than its spatial counterpart a_s . This allows better separation of the different exponentials. Using a combination of these and other technical improvements extensive excited-state spectra have recently been obtained [42,44].

17.2.3. Three-point functions:

Weak matrix elements needed to calculate semileptonic form factors and neutral meson mixing amplitudes can be computed from three-point correlation functions. We discuss here, as a representative example, the $D \to K$ amplitude. As in the case of two-point correlation functions one constructs operators O_D and O_K having overlap, respectively, with the D and K mesons. We are interested in calculating the matrix element $\langle K|V_{\mu}|D\rangle$, with $V_{\mu}=\bar{c}\gamma_{\mu}s$ the vector current. To obtain this, we use the three-point correlator

$$C_{KV\mu D}(t_x, t_y; \vec{p}) = \sum_{\vec{x}, \vec{y}} \langle O_K(t_x, \vec{x}) V_\mu(0) O_D^{\dagger}(t_y, \vec{y}) \rangle e^{-i\vec{p} \cdot \vec{x}}, \quad (17.10)$$

and focus on the limit $t_x\to\infty$, $t_y\to-\infty$. In this example we set the D-meson at rest while the kaon carries three-momentum \vec{p} . Momentum conservation then implies that the weak operator V_μ inserts three-momentum $-\vec{p}$. Inserting a pair of complete sets of states between each pair of operators, we find

$$\times \langle 0|O_K(t_x, \vec{x})|K_i(\vec{p})\rangle \langle K_i(\vec{p})|V_{\mu}(0)|D_j(\vec{0})\rangle \langle D_j(\vec{0})|O_D^{\dagger}(0)|0\rangle. \tag{17.11}$$

The matrix element $\langle K_i(\vec{p})|V_{\mu}(0)|D_j(\vec{0})\rangle$ can then be extracted, since all other quantities in this expression can be obtained from two-point correlation functions. Typically one is interested in the weak matrix elements of ground states, such as the lightest pseudoscalar mesons. In the limit of large separation between the three operators in Euclidean time, the three-point correlation function yields the weak matrix element of the transition between ground states.

17.2.4. Scattering amplitudes and resonances:

The methods described thus far yield matrix elements involving single, stable particles (where by stable here we mean absolutely stable to strong interaction decays). Most of the particles listed in the Review of Particle Properties are, however, unstable—they are resonances decaying into final states consisting of multiple strongly interacting particles. LQCD simulations cannot directly calculate resonance properties, but methods have been developed to do so indirectly for resonances coupled to two-particle final states in the elastic regime [45].

The difficulty faced by LQCD calculations is that, to obtain resonance properties, or, more generally, scattering phase-shifts, one must calculate multiparticle scattering amplitudes in momentum space and put the external particles on their mass-shells. This requires analytically continuing from Euclidean to Minkowski momenta. Although it is straightforward in LQCD to generalize the methods described above to calculate four- and higher-point correlation functions, one necessarily obtains them at a discrete and finite set of Euclidean momenta. Analytic continuation to $p_E^2 = -m^2$ is then an ill-posed and numerically unstable problem. The same problem arises for single-particle states, but can be overcome by picking out the exponential fall-off of the Euclidean correlator, as described above. With a multi-particle state, however, there is no corresponding trick, except for two particles at threshold [46].

What LQCD can calculate are the energies of the eigenstates of the QCD Hamiltonian in a finite box. The energies of states containing two stable particles, e.g. two pions, clearly depend on the interactions between the particles. It is possible to invert this dependence and, with plausible assumptions, determine the scattering phase-shifts at a discrete set of momenta from a calculation of the two-particle energy levels for a variety of spatial volumes [45]. This is a challenging calculation, but it has recently been carried through for pions with $m_{\pi} \sim 300-400$ MeV for the I=2 $\pi\pi$ system (where there is no resonance) [47] and for the I=1 system, where the parameters of the ρ resonance can be determined from the phase shifts (ignoring the small inelasticity) [48,49]. Extensions to nucleon interactions are also being actively studied [50].

It is also possible to extend the methodology to calculate electroweak decay amplitudes to two particles below the inelastic threshold, e.g. $\Gamma(K \to \pi\pi)$ [51]. First results using this methodology are now appearing. An extension to decays above the elastic threshold, e.g. hadronic B decays, has yet to be formulated.

17.2.5. Status of LQCD simulations:

Until the 1990s, most large-scale lattice simulations were limited to the "quenched" approximation, wherein the fermion determinant is omitted from the path integral. While much of the basic methodology was developed in this era, the results obtained had uncontrolled systematic errors and were not suitable for use in placing precision constraints on the Standard Model. During the 1990s, more extensive simulations including the fermion determinant (also known as simulations with "dynamical" fermions) were begun, but with unphysically high quark masses ($m_{\ell} \sim 50 - 100 \text{ MeV}$), such that the extrapolation to the physical light quark masses was a source of large systematic errors [52]. In the last 5-10 years, advances in both algorithms and computers have allowed simulations to reach much smaller quark masses ($m_{\ell} \sim 10-20 \text{ MeV}$) and even, as noted above, to work at the physical light quark mass [34]. The net effect is that LQCD calculations of selected quantities now have all sources of error controlled and small, such that they can be used effectively in phenomenological analyses.

On a more qualitative level, analytic and numerical results from LQCD have demonstrated that QCD confines color and spontaneously breaks chiral symmetry. Confinement can be seen as a linearly rising potential between heavy quark and anti-quark in the absence of quark loops. Analytically, this can be shown in the strong coupling limit $g_{\rm lat} \to \infty$ [1]. At weaker couplings there are precise numerical calculations of the potential that clearly show that this behavior persists in the continuum limit [2,3,4].

Chiral symmetry breaking was also demonstrated in the strong coupling limit on the lattice [12,53], and there have been a number of numerical studies showing that this holds also in the continuum limit. The accumulation of low-lying modes of the Dirac operator, which is the analog of Cooper pair condensation in superconductors, has been observed, yielding a determination of the chiral condensate [54]. Many relations among physical quantities that can be derived under the assumption of broken chiral symmetry have been confirmed by a number of lattice groups.

17.3. Physics applications

In this section we describe the main applications of LQCD that are both computationally mature and relevant for the determination of particle properties.

A general feature to keep in mind is that, since there are many different choices for lattice actions, all of which lead to the same continuum theory, a crucial test is that results for any given quantity are consistent. In many cases, different lattice calculations are completely independent and often have very different systematic errors. Thus final agreement, if found, is a highly non-trivial check, just as it is for different experimental measurements.

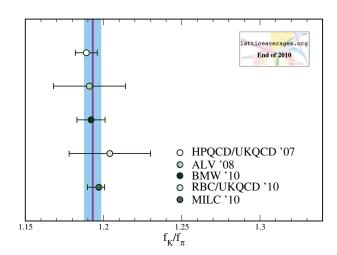

Figure 17.1: Results for f_K/f_π from simulations with $N_f=2+1$. These are from the HPQCD/UKQCD [29], ALV [58], BMW [60], RBC/UKQCD [61] and MILC [62] collaborations. The resulting average is 1.1931 ± 0.0053 .

17.3.1. Spectrum:

The most basic prediction of LQCD is of the hadron spectrum. Once the input parameters are fixed as described in Sec. 17.1.4, the masses or resonance parameters of all other states can be predicted. This includes hadrons composed of light $(u,\ d\ {\rm and}\ s)$ quarks, as well as heavy-light and heavy-heavy hadrons. It also includes quark-model exotics (e.g. $J^{PC}=1^{-+}$ mesons) and glueballs. Thus, in principle, LQCD calculations should be able to reproduce many of the experimental results compiled in the Review of Particle Properties. Doing so would test both that the error budgets of LQCD calculations are accurate and that QCD indeed describes the strong interactions in the low-energy domain. The importance of the latter test can hardly be overstated.

What is the status of this fundamental test? As discussed in Sec. 17.2, LQCD calculations are most straightforward for stable, low-lying hadrons. Resonances which can decay into only two particles are more challenging, though ultimately tractable, while those with decays to more than two particles are not yet accessible. It is also more challenging to calculate masses of flavor singlet states (which can annihilate into purely gluonic intermediate states) than those of flavor non-singlets. The present status for light hadrons is that fully controlled results are available for the masses of the octet light baryons, while results with less than complete control are available for the decuplet baryon resonances, the vector meson resonances and the η and η' . There are more extensive results for heavy-light (D and B systems) and heavy-heavy (J/ψ and Υ systems). All present results, which are discussed in the "Quark Model" review, are consistent with experimental values.

17.3.2. Decay constants and bag parameters:

The pseudoscalar decay constants can be determined from two point correlation functions involving the axial-vector current, as discussed in Sec. 17.2.2. The decay constant f_P of a meson P is extracted from the weak matrix element involving the axial-vector current using the relation $\langle 0|A_{\mu}(x)|P(\vec{p})\rangle = f_P p_{\mu} \exp(-ip \cdot x)$, where p_{μ} is the momentum of P and $A_{\mu}(x)$ is the axial-vector current. For the pion and kaon decay constants, this calculation is by now straightforward. The ratio f_K/f_{π} is especially important for the extraction of $|V_{us}|/|V_{ud}|$ from experiment, and many of the systematic errors in the lattice calculation cancel or are significantly reduced when forming the ratio. A number of lattice groups have calculated this ratio with precision at the percent level or better; all the results are in good agreement, with sub-percent precision in the world average [55,56]. A recent summary from Ref. [57] is shown in Fig. 17.1.

The heavy-light decay constants f_D and f_{D_s} involve a charm valence quark, which requires special treatment because of the relatively large charm quark mass. The different approaches in use have been discussed in Sec. 17.1.3. The HISQ action allows the charm quark to be treated in the same way as the light quarks, and has enabled HPQCD to quote precise values for the charm decay constants [29]. Calculations using less improved quark actions give consistent results, but with larger errors [59,63].

The bottom meson decay constants f_B and f_{B_s} require a valence b quark. Lattice calculations of these quantities are available using the Fermilab formulation or NRQCD to treat the bottom quark (from Refs. [64] and [65], respectively), or using an interpolation between results from around m_c to infinite quark mass [66].

The kaon bag parameter B_K is needed to turn the precise measurement of CP-violation in kaon mixing into a constraint on the Standard Model. It is defined by

$$\frac{8}{3}m_K^2 f_K^2 B_K(\mu) = \langle \overline{K}^0 | Q_{\Delta_S = 2}(\mu) | K^0 \rangle, \tag{17.12}$$

where m_K is the kaon mass, f_K is the kaon decay constant, $Q_{\Delta S=2}=\overline{s}\gamma_{\mu}(1-\gamma_5)d\overline{s}\gamma_{\mu}(1-\gamma_5)d$ is the four-quark operator of the effective electroweak Hamiltonian and μ is the renormalization scale. The short distance contribution to the electroweak Hamiltonian can be calculated perturbatively, but the long-distance matrix element parameterized by B_K must be computed using non-perturbative methods. In order to be of use to phenomenology, the renormalization factor of the four-quark operator must be matched to a continuum renormalization scheme, e.g. to \overline{MS} , as described in Sec. 17.1.5.4. Determinations with percent-level precision using different fermion actions are now available with DWF [67], staggered fermions [68], DWF valence on staggered sea quarks [69], twisted mass fermions [70] and Wilson fermions [71]. The results are all consistent.

The bag parameters for B and B_s meson mixing are defined analogously to that of kaon mixing. The B and B_s mesons contain a valence b-quark so that calculations of these quantities must use one of the methods for heavy quarks described above. These quantities have been calculated by HPQCD using NRQCD for the b-quark [65]. The ratio $\xi = f_{B_s} \sqrt{B_{B_s}}/(f_B\sqrt{B_B})$ is especially useful in CKM studies because many of the lattice systematic uncertainties cancel in the ratio, including most of the operator matching needed to convert to a continuum scheme. The dominant error in the ratio is the error associated with the chiral extrapolation of the light quark masses. The ratio ξ has been calculated in unquenched LQCD using different treatments for the b-quark [65,72], with results that are consistent.

The results discussed in this section are used in the reviews "The CKM Quark-Mixing Matrix," " V_{ud} , V_{us} , the Cabibbo Angle and CKM Unitarity," and " $B_0 - \bar{B}_0$ Mixing."

17.3.3. Form factors ($K \to \pi \ell \nu, D \to K \ell \nu, B \to \pi \ell \nu, B \to D^{(*)} \ell \nu$):

Semileptonic decay rates can be used to extract CKM matrix elements once the semileptonic form factors are known from lattice calculations. For example, the matrix element of a pseudoscalar meson P undergoing semileptonic decay to another pseudoscalar meson D is mediated by the vector current, and can be written in terms of form factors as

$$\langle D(p_D)|V_{\mu}|P(p_P)\rangle = f_{+}(q^2)(p_D + p_P - \Delta)_{\mu} + f_0(q^2)\Delta_{\mu},$$
 (17.13)

where $q = p_D - p_P$, $\Delta_{\mu} = (m_D^2 - m_P^2)q_{\mu}/q^2$ and V_{μ} is the quark vector current. The shape of the form factor is typically well determined by experiment, and the value of $f_+(q^2)$ at some reference value of q^2 is needed from the lattice in order to extract CKM matrix elements. Typically $f_+(q^2)$ dominates the decay rate, since the contribution from $f_0(q^2)$ is suppressed when the final state lepton is light.

The form factor $f_{+}(0)$ for $K \to \pi \ell \nu$ decays is highly constrained by the Ademollo-Gatto theorem [73] and chiral symmetry. Old estimates using chiral perturbation theory combined with quark models quote sub-percent precision [74], though they suffer from some model dependence. The lattice has now matched this precision while also

eliminating the model dependence; good agreement with the old estimate is found [75,76].

Charm meson semileptonic decays have been calculated by different groups using methods similar to those used for charm decay constants, and results are steadily improving in precision [77,78,79]. For semileptonic decays involving a bottom quark, one uses HQET or NROCD to control the discretization errors of the bottom quark. The form factors for the semileptonic decay $B \to \pi \ell \nu$ have been calculated in unquenched lattice QCD by two groups: HPQCD [80] and the Fermilab/MILC Collaborations [81]. These B semileptonic form factors are difficult to calculate at low q^2 , i.e. when the momentum transfer to the leptons is small and the pion carries significant momentum. The low q^2 region has large discretization errors and very large statistical errors, while the high q^2 region is much more accessible to the lattice. For experiment, the opposite is true. To combine lattice and experimental results it has proved helpful to use the z-parameter expansion [82]. This provides a theoretically constrained parameterization of the entire q^2 range, and allows one to obtain $|V_{ub}|$ with minimal model dependence [83,81].

The semileptonic decays $B\to D\ell\nu$ and $B\to D^*\ell\nu$ can be used to extract $|V_{cb}|$ once the corresponding form factors are known. At present only one unquenched calculation exists for the $B\to D^*\ell\nu$ form factor, where the Fermilab formulation of the heavy quark was adopted [84]. This calculation is done at zero-recoil because that is where the lattice systematic errors are smallest. Calculations of the necessary form factors for both processes at non-zero recoil have been done in the quenched approximation [85]. using a step-scaling approach for the heavy quarks. Lattice calculations at non-zero recoil are needed in order to decrease the error associated with the extrapolation of the experimental data to the zero-recoil point.

The results discussed in this section are used in the reviews "The CKM Quark-Mixing Matrix," " V_{ud} , V_{us} , the Cabibbo Angle and CKM Unitarity," and " V_{cb} and V_{ub} CKM Matrix Elements."

$17.3.4. \ \ Strong\ coupling\ constant:$

As explained in Sec. 17.1.4.1, for a given lattice action, the choice of bare lattice coupling constant, $g_{\rm lat}$, determines the lattice spacing a. If one then calculates a as described in Sec. 17.1.4.1, one knows the strong coupling constant in the bare lattice scheme at the scale 1/a, $\alpha_{\rm lat} = g_{\rm lat}^2/(4\pi)$. This is not, however, useful for comparing to results for α_s obtained from experiment. This is because the latter results give α_s in the $\overline{\rm MS}$ scheme, and the conversion factor between these two schemes is known to converge extremely poorly in perturbation theory. Instead one must use a method which directly determines α_s in a scheme closer to $\overline{\rm MS}$.

Several such methods have been used, all following a similar strategy. One calculates a short-distance quantity K both perturbatively $(K^{\rm PT})$ and non-perturbatively $(K^{\rm NP})$ on the lattice, and requires equality: $K^{\rm NP}=K^{\rm PT}=\sum_{i=0}^n c_i \alpha_s^i$. Solving this equation one obtains α_s at a scale related to the quantity being used. Often, α_s thus obtained is not defined in the conventional $\overline{\rm MS}$ scheme, and one has to convert among the different schemes using perturbation theory. Unlike for the bare lattice scheme, the required conversion factors are reasonably convergent. As a final step, one uses the renormalization group to run the resulting coupling to a canonical scale (such as M_Z).

In the work of the HPQCD collaboration [86], the short-distance quantities are Wilson loops of several sizes and their ratios, which are perturbatively calculated to $\mathcal{O}(\alpha_s^3)$ using the V-scheme defined through the heavy quark potential. The coefficients of even higher orders are estimated with the lattice data at various values of a.

Another choice of short-distance quantities are current-current correlators. Appropriate moments of these correlators are ultraviolet finite, and by matching lattice results to the *continuum* perturbative predictions, one can directly extract the $\overline{\rm MS}$ coupling. The JLQCD collaboration [87] uses this approach with light overlap fermions, while the HPQCD collaboration uses charm-quark correlators and HISQ fermions [88].

With a definition of α_s given using the Schrödinger functional, one can non-perturbatively control the evolution of α_s to high-energy scales, such as 100 GeV, where the perturbative expansion converges

very well. This method developed by the ALPHA collaboration [37] has been applied to 2+1-flavor QCD by the PACS-CS collaboration [89].

Results are summarized in the review of "Quantum Chromodynamics".

17.3.5. Quark masses:

Once the quark mass parameters are tuned in the lattice action, the remaining task is to convert them to those of the conventional definition. Since the quarks do not appear as asymptotic states due to confinement, the pole mass of the quark propagator is not a physical quantity. Instead, one defines the quark mass after subtracting the ultra-violet divergences in some particular way. The conventional choice is again the $\overline{\rm MS}$ scheme at a canonical scale such as 2 or 3 GeV.

As discussed in Sec. 17.1.5.4, one must convert the lattice bare quark mass to that in the $\overline{\rm MS}$ scheme. The most common approaches used for doing so are perturbation theory and the NPR method, the latter using an RI/MOM intermediate scheme.

Alternatively, one can use a definition based on the Schrödinger functional, which allows one to evolve the quark mass to a high scale non-perturbatively [90]. In practice, one can reach scales as high as ~ 100 GeV, at which matching to the $\overline{\rm MS}$ scheme can be reliably calculated in perturbation theory.

Another approach available for heavy quarks is to match currentcurrent correlators at short distances calculated on the lattice to those obtained in continuum perturbation theory in the $\overline{\rm MS}$ scheme. This has allowed an accurate determination of $m_c(\overline{\rm MS})$ [91].

Results are summarized in the review of "Quark Masses".

17.3.6. Other applications:

In this review we have concentrated on applications of LQCD that are relevant to the quantities discussed in the Review of Particle Properties. We have not discussed at all several other applications which are being actively pursued by simulations. Here we list the major such applications. The reader can consult the texts [2,3,4] for further details.

LQCD can be used, in principle, to simulate QCD at non-zero temperature and density, and in particular to study how confinement and chiral-symmetry breaking are lost as T and μ (the chemical potential) are increased. This is of relevance to heavy-ion collisions, the early Universe and neutron-star structure. In practice, finite temperature simulations are computationally tractable and relatively mature, while simulations at finite μ suffer from a "sign problem" and are at a rudimentary stage.

Another topic under active investigation is nucleon structure (generalized structure functions) and inter-nucleon interactions.

Finally, we note that there is much recent interest in studying QCD-like theories with more fermions, possibly in other representations of the gauge group. The main interest is to find nearly conformal theories which might be candidates for "walking technicolor" models.

17.4. Outlook

While LQCD calculations have made major strides in the last decade, and are now playing an important role in constraining the Standard Model, there are many calculations that could be done in principle but are not yet mature due to limitations in computational resources. As we move to exascale resources (e.g. 10^{18} floating point operations per second), the list of mature calculations will grow. Examples that we expect to mature in the next few years are results for excited hadrons, including quark-model exotics; $\langle N|\bar{s}s|N\rangle$ and related matrix elements (needed for dark-matter searches); results for moments of structure functions; $K \to \pi\pi$ amplitudes (allowing a prediction of ϵ'/ϵ from the Standard Model); $\bar{K} \leftrightarrow K$ and $\bar{B} \leftrightarrow B$ mixing amplitudes from operators arising in models of new physics (allowing one to constrain these models in a manner complementary to the direct searches at the LHC); hadronic vacuum polarization contributions to muon q-2, the running of $\alpha_{\rm EM}$ and α_s ; $\pi \to \gamma \gamma$ and related amplitudes; and perhaps the long-distance contribution to $\overline{K} \leftrightarrow K$ mixing and the light-by-light contribution to muon g-2. There will also be steady improvement in the precision attained

for the mature quantities discussed above. As already noted, this will ultimately require simulations with $m_u \neq m_d$ and including electromagnetic effects.

17.5. Acknowledgments

18. STRUCTURE FUNCTIONS

Updated July 2011 by B. Foster (University of Hamburg/DESY), A.D. Martin (University of Durham), and M.G. Vincter (Carleton University).

18.1. Deep inelastic scattering

High-energy lepton-nucleon scattering (deep inelastic scattering) plays a key role in determining the partonic structure of the proton. The process $\ell N \to \ell' X$ is illustrated in Fig. 18.1. The filled circle in this figure represents the internal structure of the proton which can be expressed in terms of structure functions.

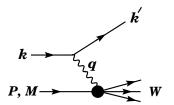

Figure 18.1: Kinematic quantities for the description of deep inelastic scattering. The quantities k and k' are the four-momenta of the incoming and outgoing leptons, P is the four-momentum of a nucleon with mass M, and W is the mass of the recoiling system X. The exchanged particle is a γ , W^{\pm} , or Z; it transfers four-momentum q = k - k' to the nucleon.

Invariant quantities:

$$\nu = \frac{q \cdot P}{M} = E - E' \text{ is the lepton's energy loss in the nucleon rest}$$
 frame (in earlier literature sometimes $\nu = q \cdot P$). Here,
 E and E' are the initial and final lepton energies in the nucleon rest frame.

$$\begin{split} Q^2 = -q^2 = 2(EE' - \overrightarrow{k} \cdot \overrightarrow{k}') - m_\ell^2 - m_{\ell'}^2 \text{ where } m_\ell(m_{\ell'}) \text{ is the initial} \\ \text{(final) lepton mass. If } EE' \sin^2(\theta/2) \gg m_\ell^2, \, m_{\ell'}^2, \, \text{then} \end{split}$$

 $\approx 4EE'\sin^2(\theta/2)$, where θ is the lepton's scattering angle with respect to the lepton beam direction.

$$x = \frac{Q^2}{2M\nu}$$
 where, in the parton model, x is the fraction of the nucleon's momentum carried by the struck quark.

$$y = \frac{q \cdot P}{k \cdot P} = \frac{\nu}{E}$$
 is the fraction of the lepton's energy lost in the nucleon

 $W^2=(P+q)^2=M^2+2M\nu-Q^2$ is the mass squared of the system X recoiling against the scattered lepton.

$$s=(k+P)^2=\frac{Q^2}{xy}+M^2+m_\ell^2 \text{ is the center-of-mass energy squared}$$
 of the lepton-nucleon system.

The process in Fig. 18.1 is called deep $(Q^2\gg M^2)$ inelastic $(W^2\gg M^2)$ scattering (DIS). In what follows, the masses of the initial and scattered leptons, m_ℓ and $m_{\ell'}$, are neglected.

$18.1.1. \ \ DIS\ cross\ sections$

$$\frac{d^2\sigma}{dx\,dy} = x\left(s - M^2\right) \frac{d^2\sigma}{dx\,dQ^2} = \frac{2\pi\,M\nu}{E'} \frac{d^2\sigma}{d\Omega_{\rm Nrest}\,dE'} \ . \tag{18.1}$$

In lowest-order perturbation theory, the cross section for the scattering of polarized leptons on polarized nucleons can be expressed in terms of the products of leptonic and hadronic tensors associated with the coupling of the exchanged bosons at the upper and lower vertices in Fig. 18.1 (see Refs. 1–4)

$$\frac{d^2\sigma}{dxdy} = \frac{2\pi y \alpha^2}{Q^4} \sum_{j} \eta_j L_j^{\mu\nu} W_{\mu\nu}^j . \qquad (18.2)$$

For neutral-current processes, the summation is over $j=\gamma,Z$ and γZ representing photon and Z exchange and the interference between

them, whereas for charged-current interactions there is only W exchange, j=W. (For transverse nucleon polarization, there is a dependence on the azimuthal angle of the scattered lepton.) $L_{\mu\nu}$ is the lepton tensor associated with the coupling of the exchange boson to the leptons. For incoming leptons of charge $e=\pm 1$ and helicity $\lambda=\pm 1$.

$$L_{\mu\nu}^{\gamma} = 2 \left(k_{\mu} k_{\nu}' + k_{\mu}' k_{\nu} - k \cdot k' g_{\mu\nu} - i \lambda \varepsilon_{\mu\nu\alpha\beta} k^{\alpha} k'^{\beta} \right),$$

$$L_{\mu\nu}^{\gamma Z} = (g_{V}^{e} + e \lambda g_{A}^{e}) L_{\mu\nu}^{\gamma}, \qquad L_{\mu\nu}^{Z} = (g_{V}^{e} + e \lambda g_{A}^{e})^{2} L_{\mu\nu}^{\gamma},$$

$$L_{\mu\nu}^{W} = (1 + e \lambda)^{2} L_{\mu\nu}^{\gamma}, \qquad (18.3)$$

where
$$g_V^e = -\frac{1}{2} \, + \, 2 \sin^2 \theta_W, \qquad g_A^e \, = \, -\frac{1}{2}$$
 .

Although here the helicity formalism is adopted, an alternative approach is to express the tensors in Eq. (18.3) in terms of the polarization of the lepton.

The factors η_j in Eq. (18.2) denote the ratios of the corresponding propagators and couplings to the photon propagator and coupling squared

$$\eta_{\gamma} = 1 \quad ; \quad \eta_{\gamma Z} = \left(\frac{G_F M_Z^2}{2\sqrt{2}\pi\alpha}\right) \left(\frac{Q^2}{Q^2 + M_Z^2}\right);$$

$$\eta_{Z} = \eta_{\gamma Z}^2 \quad ; \quad \eta_{W} = \frac{1}{2} \left(\frac{G_F M_W^2}{4\pi\alpha} \frac{Q^2}{Q^2 + M_W^2}\right)^2. \quad (18.4)$$

The hadronic tensor, which describes the interaction of the appropriate electroweak currents with the target nucleon, is given by

$$W_{\mu\nu} = \frac{1}{4\pi} \int d^4z \, e^{iq\cdot z} \left\langle P, S \left| \left[J_{\mu}^{\dagger}(z), J_{\nu}(0) \right] \right| P, S \right\rangle, \tag{18.5}$$

where S denotes the nucleon-spin 4-vector, with $S^2=-M^2$ and $S\cdot P=0.$

18.2. Structure functions of the proton

The structure functions are defined in terms of the hadronic tensor (see Refs. 1–3)

$$\begin{split} W_{\mu\nu} &= \left(-g_{\mu\nu} \, + \, \frac{q_{\mu}q_{\nu}}{q^2} \right) \, F_1(x,Q^2) + \frac{\hat{P}_{\mu}\hat{P}_{\nu}}{P \cdot q} \, F_2(x,Q^2) \\ &- \, i\varepsilon_{\mu\nu\alpha\beta} \, \frac{q^{\alpha}P^{\beta}}{2P \cdot q} \, F_3(x,Q^2) \\ &+ \, i\varepsilon_{\mu\nu\alpha\beta} \, \frac{q^{\alpha}}{P \cdot q} \, \left[S^{\beta}g_1(x,Q^2) + \left(S^{\beta} \, - \, \frac{S \cdot q}{P \cdot q} \, P^{\beta} \right) \, g_2(x,Q^2) \right] \\ &+ \, \frac{1}{P \cdot q} \, \left[\frac{1}{2} \left(\hat{P}_{\mu}\hat{S}_{\nu} \, + \, \hat{S}_{\mu}\hat{P}_{\nu} \right) - \frac{S \cdot q}{P \cdot q} \, \hat{P}_{\mu}\hat{P}_{\nu} \right] \, g_3(x,Q^2) \\ &+ \, \frac{S \cdot q}{P \cdot q} \, \left[\frac{\hat{P}_{\mu}\hat{P}_{\nu}}{P \cdot q} \, g_4(x,Q^2) + \left(-g_{\mu\nu} \, + \, \frac{q_{\mu}q_{\nu}}{q^2} \right) \, g_5(x,Q^2) \right] (18.6) \end{split}$$

where

$$\hat{P}_{\mu} = P_{\mu} - \frac{P \cdot q}{q^2} q_{\mu}, \qquad \hat{S}_{\mu} = S_{\mu} - \frac{S \cdot q}{q^2} q_{\mu}.$$
 (18.7)

In Ref. 2, the definition of $W_{\mu\nu}$ with $\mu \leftrightarrow \nu$ is adopted, which changes the sign of the $\varepsilon_{\mu\nu\alpha\beta}$ terms in Eq. (18.6), although the formulae given here below are unchanged. Ref. 1 tabulates the relation between the structure functions defined in Eq. (18.6) and other choices available in the literature.

The cross sections for neutral- and charged-current deep inelastic scattering on unpolarized nucleons can be written in terms of the structure functions in the generic form

$$\frac{d^2 \sigma^i}{dxdy} = \frac{4\pi\alpha^2}{xyQ^2} \eta^i \left\{ \left(1 - y - \frac{x^2 y^2 M^2}{Q^2} \right) F_2^i + y^2 x F_1^i \mp \left(y - \frac{y^2}{2} \right) x F_3^i \right\},$$
(18.8)

where $i={
m NC},{
m CC}$ corresponds to neutral-current $(eN\to eX)$ or charged-current $(eN\to \nu X$ or $\nu N\to eX)$ processes, respectively. For incoming neutrinos, $L_{\mu\nu}^W$ of Eq. (18.3) is still true, but with e,λ corresponding to the outgoing charged lepton. In the last term of Eq. (18.8), the - sign is taken for an incoming e^+ or $\overline{\nu}$ and the + sign for an incoming e^- or ν . The factor $\eta^{\rm NC}=1$ for unpolarized e^\pm beams, whereas*

$$\eta^{\rm CC} = (1 \pm \lambda)^2 \eta_W \tag{18.9}$$

with \pm for ℓ^{\pm} ; and where λ is the helicity of the incoming lepton and η_W is defined in Eq. (18.4); for incoming neutrinos $\eta^{\rm CC} = 4\eta_W$. The CC structure functions, which derive exclusively from W exchange, are

$$F_1^{\text{CC}} = F_1^W, \ F_2^{\text{CC}} = F_2^W, \ xF_3^{\text{CC}} = xF_3^W.$$
 (18.10)

The NC structure functions $F_2^{\gamma}, F_2^{\gamma Z}, F_2^{Z}$ are, for $e^{\pm}N \to e^{\pm}X$, given by Ref. 5,

$$F_2^{\text{NC}} = F_2^{\gamma} - (g_V^e \pm \lambda g_A^e) \eta_{\gamma Z} F_2^{\gamma Z} + (g_V^{e^2} + g_A^{e^2} \pm 2\lambda g_V^e g_A^e) \eta_Z F_2^{Z}$$
(18.11)

and similarly for F_1^{NC} , whereas

$$xF_{3}^{\rm NC} = -(g_A^e \pm \lambda g_V^e)\eta_{\gamma Z} xF_{3}^{\gamma Z} + [2g_V^e g_A^e \pm \lambda (g_V^{e^2} + g_A^{e^2})]\eta_Z xF_{3}^Z \ . \eqno(18.12)$$

The polarized cross-section difference

$$\Delta \sigma = \sigma(\lambda_n = -1, \lambda_\ell) - \sigma(\lambda_n = 1, \lambda_\ell) , \qquad (18.13)$$

where $\lambda_{\ell}, \lambda_n$ are the helicities (± 1) of the incoming lepton and nucleon, respectively, may be expressed in terms of the five structure functions $g_{1,\dots,5}(x,Q^2)$ of Eq. (18.6). Thus,

$$\frac{d^2 \Delta \sigma^i}{dx dy} \; = \; \frac{8 \pi \alpha^2}{x y Q^2} \; \eta^i \left\{ -\lambda_\ell y \left(2 - y - 2 x^2 y^2 \frac{M^2}{Q^2} \right) \; x g_1^i + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \; g_2^i \right\} \; dx dy + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \; g_2^i + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \; g_2^i + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \; g_2^i + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \; g_2^i + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \; g_2^i + \lambda_\ell 4 x^3 y^2 \; \frac{M^2}{Q^2} \;$$

$$+ \ 2 x^2 y \frac{M^2}{Q^2} \left(1 - y - x^2 y^2 \frac{M^2}{Q^2} \right) \ g_3^i$$

$$- \left(1 + 2x^2 y \frac{M^2}{Q^2}\right) \left[\left(1 - y - x^2 y^2 \frac{M^2}{Q^2}\right) g_4^i + x y^2 g_5^i \right] \right\}$$
 (18.14)

with $i=\mathrm{NC}$ or CC as before. The Eq. (18.13) corresponds to the difference of antiparallel minus parallel spins of the incoming particles for e^- or ν initiated reactions, but the difference of parallel minus antiparallel for e^+ or $\overline{\nu}$ initiated processes. For longitudinal nucleon polarization, the contributions of g_2 and g_3 are suppressed by powers of M^2/Q^2 . These structure functions give an unsuppressed contribution to the cross section for transverse polarization [1], but in this case the cross-section difference vanishes as $M/Q \to 0$.

Because the same tensor structure occurs in the spin-dependent and spin-independent parts of the hadronic tensor of Eq. (18.6) in the $M^2/Q^2 \to 0$ limit, the differential cross-section difference of Eq. (18.14) may be obtained from the differential cross section Eq. (18.8) by replacing

$$F_1 \rightarrow -g_5 , \quad F_2 \rightarrow -g_4 , \quad F_3 \rightarrow 2g_1 , \qquad (18.15)$$

and multiplying by two, since the total cross section is the average over the initial-state polarizations. In this limit, Eq. (18.8) and Eq. (18.14) may be written in the form

$$\frac{d^2\sigma^i}{dxdy} = \frac{2\pi\alpha^2}{xyQ^2} \eta^i \left[Y_+ F_2^i \mp Y_- x F_3^i - y^2 F_L^i \right],
\frac{d^2\Delta\sigma^i}{dxdy} = \frac{4\pi\alpha^2}{xyQ^2} \eta^i \left[-Y_+ g_4^i \mp Y_- 2x g_1^i + y^2 g_L^i \right],$$
(18.16)

with i = NC or CC, where $Y_{+} = 1 \pm (1 - y)^{2}$ and

$$F_L^i = F_2^i - 2xF_1^i, g_L^i = g_4^i - 2xg_5^i. (18.17)$$

In the naive quark-parton model, the analogy with the Callan-Gross relations [6] $F_L^i = 0$, are the Dicus relations [7] $g_L^i = 0$. Therefore, there are only two independent polarized structure functions: g_1 (parity conserving) and g_5 (parity violating), in analogy with the unpolarized structure functions F_1 and F_3 .

18.2.1. Structure functions in the quark-parton model:

In the quark-parton model [8,9], contributions to the structure functions F^i and g^i can be expressed in terms of the quark distribution functions $q(x,Q^2)$ of the proton, where $q=u,\overline{u},d,\overline{d}$ etc. The quantity $q(x,Q^2)dx$ is the number of quarks (or antiquarks) of designated flavor that carry a momentum fraction between x and x+dx of the proton's momentum in a frame in which the proton momentum is large.

For the neutral-current processes $ep \rightarrow eX$,

$$\begin{split} \left[F_{2}^{\gamma},\ F_{2}^{\gamma Z},\ F_{2}^{Z}\right] &= x \sum_{q} \left[e_{q}^{2},\ 2e_{q}g_{V}^{q},\ g_{V}^{q\,2} + g_{A}^{q\,2}\right]\ (q + \overline{q})\ , \\ \left[F_{3}^{\gamma},\ F_{3}^{\gamma Z},\ F_{3}^{Z}\right] &= \sum_{q} \left[0,\ 2e_{q}g_{A}^{q},\ 2g_{V}^{q}g_{A}^{q}\right]\ (q - \overline{q})\ , \\ \left[g_{1}^{\gamma},\ g_{1}^{\gamma Z},\ g_{1}^{Z}\right] &= \frac{1}{2} \sum_{q} \left[e_{q}^{2},\ 2e_{q}g_{V}^{q},\ g_{V}^{q\,2} + g_{A}^{q\,2}\right]\ (\Delta q + \Delta \overline{q})\ , \\ \left[g_{5}^{\gamma},\ g_{5}^{\gamma Z},\ g_{5}^{Z}\right] &= \sum_{q} \left[0,\ e_{q}g_{A}^{q},\ g_{V}^{q}g_{A}^{q}\right]\ (\Delta q - \Delta \overline{q})\ , \end{split} \tag{18.18}$$

where $g_V^q = \pm \frac{1}{2} - 2e_q \sin^2 \theta_W$ and $g_A^q = \pm \frac{1}{2}$, with \pm according to whether q is a u- or d-type quark respectively. The quantity Δq is the difference $q\uparrow - q\downarrow$ of the distributions with the quark spin parallel and antiparallel to the proton spin.

For the charged-current processes $e^-p \to \nu X$ and $\overline{\nu}p \to e^+X$, the structure functions are:

$$F_{2}^{W^{-}} = 2x(u + \overline{d} + \overline{s} + c \dots) ,$$

$$F_{3}^{W^{-}} = 2(u - \overline{d} - \overline{s} + c \dots) ,$$

$$g_{1}^{W^{-}} = (\Delta u + \Delta \overline{d} + \Delta \overline{s} + \Delta c \dots) ,$$

$$g_{5}^{W^{-}} = (-\Delta u + \Delta \overline{d} + \Delta \overline{s} - \Delta c \dots) ,$$

$$(18.19)$$

where only the active flavors are to be kept and where CKM mixing has been neglected. For $e^+p \to \overline{\nu} X$ and $\nu p \to e^- X$, the structure functions F^{W^+}, g^{W^+} are obtained by the flavor interchanges $d \leftrightarrow u, s \leftrightarrow c$ in the expressions for F^{W^-}, g^{W^-} . The structure functions for scattering on a neutron are obtained from those of the proton by the interchange $u \leftrightarrow d$. For both the neutral- and charged-current processes, the quark-parton model predicts $2xF_1^i=F_2^i$ and $g_4^i=2xg_5^i$.

Neglecting masses, the structure functions g_2 and g_3 contribute only to scattering from transversely polarized nucleons (for which $S \cdot q = 0$), and have no simple interpretation in terms of the quark-parton model. They arise from off-diagonal matrix elements $\langle P, \lambda' | [J^{\dagger}_{\mu}(z), J_{\nu}(0)] | P, \lambda \rangle$, where the proton helicities satisfy $\lambda' \neq \lambda$. In fact, the leading-twist contributions to both g_2 and g_3 are both twist-2 and twist-3, which contribute at the same order of Q^2 . The Wandzura-Wilczek relation [10] expresses the twist-2 part of g_2 in terms of g_1 as

$$g_2^i(x) = -g_1^i(x) + \int_x^1 \frac{dy}{y} g_1^i(y)$$
 (18.20)

However, the twist-3 component of g_2 is unknown. Similarly, there is a relation expressing the twist-2 part of g_3 in terms of g_4 . A complete set of relations, including M^2/Q^2 effects, can be found in Ref. 11.

18.2.2. Structure functions and QCD:

One of the most striking predictions of the quark-parton model is that the structure functions F_i,g_i scale, i.e., $F_i(x,Q^2)\to F_i(x)$ in the Bjorken limit that Q^2 and $\nu\to\infty$ with x fixed [12]. This property is related to the assumption that the transverse momentum of the partons in the infinite-momentum frame of the proton is small. In QCD, however, the radiation of hard gluons from the quarks violates this assumption, leading to logarithmic scaling violations, which are particularly large at small x, see Fig. 18.2. The radiation of gluons produces the evolution of the structure functions. As Q^2 increases, more and more gluons are radiated, which in turn split into $q\overline{q}$ pairs. This process leads both to the softening of the initial quark momentum distributions and to the growth of the gluon density and the $q\overline{q}$ sea as x decreases.

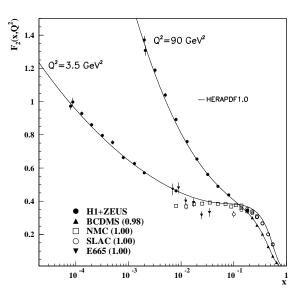

Figure 18.2: The proton structure function F_2^p given at two Q^2 values (3.5 GeV² and 90 GeV²), which exhibit scaling at the 'pivot' point $x \sim 0.14$. See the captions in Fig. 18.8 and Fig. 18.10 for the references of the data. The various data sets have been renormalized by the factors shown in brackets in the key to the plot, which were globally determined in the full HERAPDF analysis [46]. In practice, data for the reduced cross section, $F_2(x,Q^2) - (y^2/Y_+)F_L(x,Q^2)$, are fitted, rather than F_2 and F_L separately.

In QCD, the above process is described in terms of scale-dependent parton distributions $f_a(x, \mu^2)$, where a = g or q and, typically, μ is the scale of the probe Q. For $Q^2 \gg M^2$, the structure functions are of the form

$$F_i = \sum_{a} C_i^a \otimes f_a, \tag{18.21}$$

where \otimes denotes the convolution integral

$$C \otimes f = \int_{x}^{1} \frac{dy}{y} C(y) f\left(\frac{x}{y}\right),$$
 (18.22)

and where the coefficient functions C_i^a are given as a power series in α_s . The parton distribution f_a corresponds, at a given x, to the density of parton a in the proton integrated over transverse momentum k_t up to μ . Its evolution in μ is described in QCD by a DGLAP equation (see Refs. 14–17) which has the schematic form

$$\frac{\partial f_a}{\partial \ln \mu^2} \sim \frac{\alpha_s(\mu^2)}{2\pi} \sum_b (P_{ab} \otimes f_b) , \qquad (18.23)$$

where the P_{ab} , which describe the parton splitting $b \to a$, are also given as a power series in α_s . Although perturbative QCD can predict, via Eq. (18.23), the evolution of the parton distribution functions from a particular scale, μ_0 , these DGLAP equations cannot predict them a priori at any particular μ_0 . Thus they must be measured at a starting point μ_0 before the predictions of QCD can be compared to the data at other scales, μ . In general, all observables involving a hard hadronic interaction (such as structure functions) can be expressed as a convolution of calculable, process-dependent coefficient functions and these universal parton distributions, e.g. Eq. (18.21).

It is often convenient to write the evolution equations in terms of the gluon, non-singlet (q^{NS}) and singlet (q^S) quark distributions, such that

$$q^{NS} = q_i - \overline{q}_i \text{ (or } q_i - q_j), \qquad q^S = \sum_i (q_i + \overline{q}_i) .$$
 (18.24)

The non-singlet distributions have non-zero values of flavor quantum numbers, such as isospin and baryon number. The DGLAP evolution

equations then take the form

$$\begin{split} \frac{\partial q^{NS}}{\partial \ln \mu^2} &= \frac{\alpha_s(\mu^2)}{2\pi} \; P_{qq} \; \otimes \; q^{NS} \; , \\ \frac{\partial}{\partial \ln \mu^2} \; \begin{pmatrix} q^S \\ g \end{pmatrix} &= \frac{\alpha_s(\mu^2)}{2\pi} \; \begin{pmatrix} P_{qq} & 2n_f \; P_{qg} \\ P_{gq} & P_{gg} \end{pmatrix} \; \otimes \; \begin{pmatrix} q^S \\ g \end{pmatrix}, (18.25) \end{split}$$

where P are splitting functions that describe the probability of a given parton splitting into two others, and n_f is the number of (active) quark flavors. The leading-order Altarelli-Parisi [16] splitting functions are

$$P_{qq} = \frac{4}{3} \left[\frac{1+x^2}{(1-x)} \right]_{\perp} = \frac{4}{3} \left[\frac{1+x^2}{(1-x)_{+}} \right] + 2\delta(1-x) ,$$
 (18.26)

$$P_{qg} = \frac{1}{2} \left[x^2 + (1 - x)^2 \right] , \qquad (18.27)$$

$$P_{gq} = \frac{4}{3} \left[\frac{1 + (1 - x)^2}{x} \right] , \qquad (18.28)$$

$$P_{gg} = 6 \left[\frac{1-x}{x} + x(1-x) + \frac{x}{(1-x)_{+}} \right] + \left[\frac{11}{2} - \frac{n_f}{3} \right] \delta(1-x),$$
 (18.29)

where the notation $[F(x)]_+$ defines a distribution such that for any sufficiently regular test function, f(x),

$$\int_0^1 dx f(x) [F(x)]_+ = \int_0^1 dx \ (f(x) - f(1)) F(x) \ . \tag{18.30}$$

In general, the splitting functions can be expressed as a power series in α_s . The series contains both terms proportional to $\ln \mu^2$ and to $\ln 1/x$. The leading-order DGLAP evolution sums up the $(\alpha_s \ln \mu^2)^n$ contributions, while at next-to-leading order (NLO) the sum over the $\alpha_s (\alpha_s \ln \mu^2)^{n-1}$ terms is included [18,19]. In fact, the NNLO contributions to the splitting functions and the DIS coefficient functions are now also all known [20–22].

In the kinematic region of very small x, it is essential to sum leading terms in $\ln 1/x$, independent of the value of $\ln \mu^2$. At leading order, LLx, this is done by the BFKL equation for the unintegrated distributions (see Refs. [23,24]). The leading-order $(\alpha_s \ln(1/x))^n$ terms result in a power-like growth, $x^{-\omega}$ with $\omega = (12\alpha_s \ln 2)/\pi$, at asymptotic values of $\ln 1/x$. More recently, the next-to-leading $\ln 1/x$ (NLLx) contributions have become available [25,26]. They are so large (and negative) that the result appears to be perturbatively unstable. Methods, based on a combination of collinear and small xresummations, have been developed which reorganize the perturbative series into a more stable hierarchy [27–30]. There are indications that small x resummations become necessary for real precision for $x \lesssim 10^{-3}$ at low scales. On the other hand, there is no convincing indication that, for $Q^2 \gtrsim 2 \text{ GeV}^2$, we have entered the 'non-linear' regime where the gluon density is so high that gluon-gluon recombination effects become significant.

The precision of the contemporary experimental data demands that at least NLO, and preferably NNLO, DGLAP evolution be used in comparisons between QCD theory and experiment. Beyond the leading order, it is necessary to specify, and to use consistently, both a renormalization and a factorization scheme. The renormalization scheme used is almost universally the modified minimal subtraction $(\overline{\rm MS})$ scheme [31,32]. There are two popular choices for factorization scheme, in which the form of the correction for each structure function is different. The most-used factorization scheme is again $\overline{\rm MS}$ [33]. However, sometimes the DIS [34] scheme is adopted, in which there are no higher-order corrections to the F_2 structure function. The two schemes differ in how the non-divergent pieces are assimilated in the parton distribution functions.

The u,d, and s quarks are taken to be massless, and the effects of the c and b-quark masses have been studied up to NNLO, for example, in [35–42]. An approach using a 'general mass variable flavor number scheme' (GM-VFNS) is now generally adopted, in which evolution

Table 18.1: The main processes relevant to global PDF analyses, ordered in three groups: fixed-target experiments, HERA and the $p\bar{p}$ Tevatron (pp LHC). For each process we give an indication of their dominant partonic subprocesses, the primary partons which are probed and the approximate range of x constrained by the data. The Table is adapted from [13].

| Process | Subprocess | Partons | x range |

with $n_f = 3$ is matched to that with $n_f = 4$ at the charm threshold, with an analogous matching at the bottom threshold.

The discussion above relates to the Q^2 behavior of leading-twist (twist-2) contributions to the structure functions. Higher-twist terms, which involve their own non-perturbative input, exist. These die off as powers of Q; specifically twist-n terms are damped by $1/Q^{n-2}$. The higher-twist terms appear to be numerically unimportant for Q^2 above a few GeV², except for x close to 1.

18.3. Determination of parton distributions

The parton distribution functions (PDFs) can be determined from data for deep inelastic lepton-nucleon scattering and for related hard-scattering processes initiated by nucleons. Table 18.1 highlights some processes and their primary sensitivity to PDFs. The kinematic ranges of fixed-target and collider experiments are complementary (as is shown in Fig. 18.3), which enables the determination of PDFs over a wide range in x and Q^2 . As precise LHC data for W^{\pm} , Z, γ , jet, $b\bar{b}$ and $t\bar{t}$ production become available, the kinematic reach of the data will further widen, and tighter constraints on the PDFs are expected.

Recent determinations of the unpolarized PDF's have been made by six groups: MSTW [13], CT(EQ) [43], NNPDF [44,45], HERAPDF [46], ABKM [47] and GJR [48,49]. Distinguishing features of the various analyses have been reviewed in [50,51]. Most groups use input PDFs of the form $xf=x^a(...)(1-x)^b$ with 10-25 free parameters in total. Note, however, that NNPDF combine a Monte Carlo representation of the probability measure in the space of PDFs with the use of neural networks to give a set of unbiased input distributions, while GJR generate 'dynamical' PDFs from a valence-like input at some very low starting scale, $Q_0^2=0.5~{\rm GeV}^2$. All groups, except CT, present PDFs at NLO and NNLO. The results of one analysis are shown in Fig. 18.4 at scales $\mu^2=10$ and $10^4~{\rm GeV}^2$.

MSTW, CT and NNPDF are 'global' analyses in that they fit to a full range of the types of data that are available (and use GM-VFNS). The most recent determinations of these three groups have converged, so that now a reasonable agreement has been achieved between the resulting PDFs, the value obtained for $\alpha_s(M_Z^2)$, and their predictions for the LHC. The values of α_s found by MSTW [13,52] may be taken

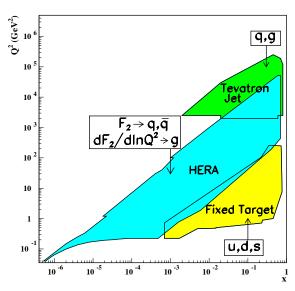

Figure 18.3: Kinematic domains in x and Q^2 probed by fixed-target and collider experiments, shown together with the parton distributions that are most strongly constrained by the indicated regions.

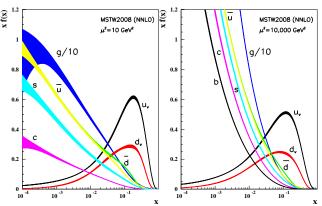

Figure 18.4: Distributions of x times the unpolarized parton distributions f(x) (where $f = u_v, d_v, \overline{u}, \overline{d}, s, c, b, g$) and their associated uncertainties using the NNLO MSTW2008 parameterization [13] at a scale $\mu^2 = 10 \text{ GeV}^2$ and $\mu^2 = 10,000 \text{ GeV}^2$.

as representative of that found in global fits to DIS and related hard scattering data $\,$

$$\begin{aligned} \text{NLO}: \alpha_s(M_Z^2) &= 0.1202^{+0.0012}_{-0.0015} \pm 0.003, \\ \text{NNLO}: \alpha_s(M_Z^2) &= 0.1171 \pm 0.0014 \pm 0.002, \end{aligned}$$

where the first error (at 68% C.L.) corresponds to the uncertainties in the data fitted and the second is an estimate of the theory error (that is, the uncertainty which might be expected at higher orders).

The PDFs of the remaining three groups are obtained without including the Tevatron W,Z production data; and the HERAPDF and ABKM groups do not fit to the Tevatron jet data. The importance of carefully including the latter data is discussed in detail in [53], and is shown to be responsible for the anomalously low value of α_s found by ABKM [47].

Spin-dependent (or polarized) PDFs have been obtained through NLO global analyses which include measurements of the g_1 structure function in inclusive polarized DIS, 'flavour-tagged' semi-inclusive DIS data, and results from polarized pp scattering at RHIC. Recent NLO analyses are given in Refs. [54–57]. Improved parton-to-hadron fragmentation functions, needed to describe the semi-inclusive DIS data, can be found in [58–60]. Fig. 18.5 shows several global analyses at a scale of 2.5 $\,\mathrm{GeV}^2$ along with the data from semi-inclusive DIS.

Comprehensive sets of PDFs are available as program-callable functions from the HepData website [66], which includes comparison graphics of PDFs, and from the LHAPDF library [67], which can be linked directly into a users programme to provide access to recent PDFs in a standard format.

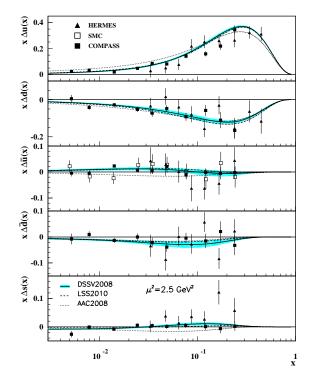

Figure 18.5: Distributions of x times the polarized parton distributions $\Delta q(x)$ (where $q=u,d,\overline{u},\overline{d},s$) using the LSS2010 [57], AAC2008 [54], and DSSV2008 [55] parameterizations at a scale $\mu^2=2.5~{\rm GeV}^2$, showing the error corridor of the latter set (corresponding to a one-unit increase in χ^2). See also BB2010 [56]. Points represent data from semi-inclusive positron (HERMES [61,62]) and muon (SMC [63] and COMPASS [64,65]) deep inelastic scattering given at $Q^2=2.5~{\rm GeV}^2$. SMC results are extracted under the assumption that $\Delta\overline{u}(x)=\Delta\overline{d}(x)$.

18.4. The hadronic structure of the photon

Besides the direct interactions of the photon, it is possible for it to fluctuate into a hadronic state via the process $\gamma \to q\overline{q}$. While in this state, the partonic content of the photon may be resolved, for example, through the process $e^+e^-\to e^+e^-\gamma^*\gamma\to e^+e^-X$, where the virtual photon emitted by the DIS lepton probes the hadronic structure of the quasi-real photon emitted by the other lepton. The perturbative LO contributions, $\gamma \to q\overline{q}$ followed by $\gamma^*q \to q$, are subject to QCD corrections due to the coupling of quarks to gluons.

Often the equivalent-photon approximation is used to express the differential cross section for deep inelastic electron–photon scattering in terms of the structure functions of the transverse quasi-real photon times a flux factor N_T^{γ} (for these incoming quasi-real photons of transverse polarization)

$$\frac{d^2\sigma}{dxdQ^2} = N_\gamma^T \frac{2\pi\alpha^2}{xQ^4} \left[\left(1+(1-y)^2\right) F_2^\gamma(x,Q^2) - y^2 F_L^\gamma(x,Q^2) \right], \label{eq:delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delta_delt$$

where we have used $F_2^{\gamma}=2xF_T^{\gamma}+F_L^{\gamma}$, not to be confused with F_2^{γ} of Sec. 18.2. Complete formulae are given, for example, in the comprehensive review of Ref. 68.

The hadronic photon structure function, F_2^γ , evolves with increasing Q^2 from the 'hadron-like' behavior, calculable via the vector-meson-dominance model, to the dominating 'point-like' behaviour, calculable in perturbative QCD. Due to the point-like coupling, the logarithmic evolution of F_2^γ with Q^2 has a positive slope for all values of x, see Fig. 18.15. The 'loss' of quarks at large x due to gluon radiation is over-compensated by the 'creation' of quarks via the point-like $\gamma \to q\bar{q}$ coupling. The logarithmic evolution was first predicted in the quark–parton model $(\gamma^*\gamma \to q\bar{q})$ [69,70], and then in QCD in the limit of large Q^2 [71]. The evolution is now known to NLO [72–74]. NLO data analyses to determine the parton densities of the photon can be found in [75–77].

18.5. Diffractive DIS (DDIS)

Some 10% of DIS events are diffractive, $\gamma^*p \to X + p$, in which the slightly deflected proton and the cluster X of outgoing hadrons are well-separated in rapidity. Besides x and Q^2 , two extra variables are needed to describe a DDIS event: the fraction $x_{I\!P}$ of the proton's momentum transferred across the rapidity gap and t, the square of the 4-momentum transfer of the proton. The DDIS data [78–83] are usually analyzed using two levels of factorization. First, the diffractive structure function F_2^D satisfies collinear factorization, and can be expressed as the convolution [84]

$$F_2^{\rm D} = \sum_{a=a,a} C_2^a \otimes f_{a/p}^{\rm D},$$
 (18.31)

with the same coefficient functions as in DIS (see Eq. (18.21)), and where the diffractive parton distributions $f_{a/p}^{\rm D}$ (a=q,g) satisfy DGLAP evolution. Second, Regge factorization is assumed [85],

$$f_{a/p}^{\rm D}(x_{I\!\!P}, t, z, \mu^2) = f_{I\!\!P/p}(x_{I\!\!P}, t) f_{a/I\!\!P}(z, \mu^2),$$
 (18.32)

where $f_{a/I\!\!P}$ are the parton densities of the Pomeron, which itself is treated like a hadron, and $z \in [x/x_{I\!\!P},1]$ is the fraction of the Pomeron's momentum carried by the parton entering the hard subprocess. The Pomeron flux factor $f_{I\!\!P/p}(x_{I\!\!P},t)$ is taken from Regge phenomenology. There are also secondary Reggeon contributions to Eq. (18.32). A sample of the t-integrated diffractive parton densities, obtained in this way, is shown in Fig. 18.6.

Although collinear factorization holds as $\mu^2 \to \infty$, there are non-negligible corrections for finite μ^2 and small $x_{I\!P}$. Besides the resolved interactions of the Pomeron, the perturbative QCD Pomeron may also interact directly with the hard subprocess, giving rise to an inhomogeneous evolution equation for the diffractive parton densities analogous to the photon case. The results of the MRW analysis [87], which includes these contributions, are also shown in Fig. 18.6. Unlike the inclusive case, the diffractive parton densities cannot be directly used to calculate diffractive hadron-hadron cross sections, since account must first be taken of "soft" rescattering effects.

18.6. Generalized parton distributions

The parton distributions of the proton of Sec. 18.3 are given by the diagonal matrix elements $\langle P, \lambda | \hat{O} | P, \lambda \rangle$, where P and λ are the 4-momentum and helicity of the proton, and \hat{O} is a twist-2 quark or gluon operator. However, there is new information in the so-called generalised parton distributions (GPDs) defined in terms of the off-diagonal matrix elements $\langle P', \lambda' | \hat{O} | P, \lambda \rangle$; see Refs. 89–93 for reviews. Unlike the diagonal PDFs, the GPDs cannot be regarded as parton densities, but are to be interpreted as probability amplitudes.

The physical significance of GPDs is best seen using light-cone coordinates, $z^{\pm}=(z^0\pm z^3)/\sqrt{2}$, and in the light-cone gauge, $A^+=0$. It is conventional to define the generalised quark distributions in terms of quark operators at light-like separation

$$\begin{split} F_{q}(x,\xi,t) &= \frac{1}{2} \int \frac{dz^{-}}{2\pi} e^{ix\bar{P}^{+}z^{-}} \langle P' | \bar{\psi}(-z/2) \gamma^{+} \psi(z/2) | P \rangle \bigg|_{z^{+}=z^{1}=z^{2}=0} \\ &= \frac{1}{2\bar{P}^{+}} \left(H_{q}(x,\xi,t) \ \bar{u}(P') \gamma^{+} u(P) \ + \ E_{q}(x,\xi,t) \ \bar{u}(P') \frac{i\sigma^{+\alpha} \Delta_{\alpha}}{2m} u(P) \right) \end{split}$$

$$(18.34)$$

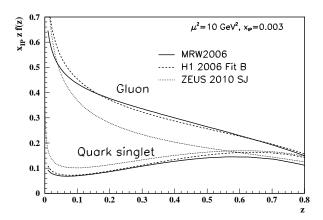

Figure 18.6: Diffractive parton distributions, $x_{I\!\!P} z f_{a/p}^D$, obtained from fitting to the ZEUS data with $Q^2 > 5 \text{ GeV}^2$ [86], H1 data with $Q^2 > 8.5 \text{ GeV}^2$ assuming Regge factorization [81], and using a more perturbative QCD approach [87]. Only the Pomeron contributions are shown and not the secondary Reggeon contributions, which are negligible at the value of $x_{I\!\!P} = 0.003$ chosen here. The H1 2007 Jets distribution [88] is similar to H1 2006 Fit B.

with $\bar{P}=(P+P')/2$ and $\Delta=P'-P$, and where we have suppressed the helicity labels of the protons and spinors. We now have two extra kinematic variables:

$$t = \Delta^2,$$
 $\xi = -\Delta^+/(P + P')^+.$ (18.35)

We see that $-1 \le \xi \le 1$. Similarly, we may define GPDs \tilde{H}_q and \tilde{E}_q with an additional γ_5 between the quark operators in Eq. (18.33); and also an analogous set of gluon GPDs, H_g , E_g , \tilde{H}_g and \tilde{E}_g . After a Fourier transform with respect to the transverse components of Δ , we are able to describe the spatial distribution of partons in the impact parameter plane in terms of GPDs [94,95].

For $P'=P,\ \lambda'=\lambda$ the matrix elements reduce to the ordinary PDFs of Sec. 18.2.1

$$H_q(x,0,0) = q(x), H_q(-x,0,0) = -\bar{q}(x), H_g(x,0,0) = xg(x),$$
(18.36)

$$\tilde{H}_q(x,0,0) = \Delta q(x), \quad \tilde{H}_q(-x,0,0) = \Delta \bar{q}(x), \quad \tilde{H}_g(x,0,0) = x\Delta g(x),$$

where $\Delta q = q \uparrow - q \downarrow$ as in Eq. (18.18). No corresponding relations exist for E, \tilde{E} as they decouple in the forward limit, $\Delta = 0$.

 H_g, E_g are even functions of x, and \tilde{H}_g, \tilde{E}_g are odd functions of x. We can introduce valence and 'singlet' quark distributions which are even and odd functions of x respectively. For example

$$H_q^V(x,\xi,t) \equiv H_q(x,\xi,t) + H_q(-x,\xi,t) = H_q^V(-x,\xi,t), \qquad (18.38)$$

$$H_q^S(x,\xi,t) \equiv H_q(x,\xi,t) - H_q(-x,\xi,t) = -H_q^S(-x,\xi,t).$$
 (18.39)

All the GPDs satisfy relations of the form

$$H(x, -\xi, t) = H(x, \xi, t)$$
 and $H(x, -\xi, t)^* = H(x, \xi, t),$
(18.40)

and so are real-valued functions. Moreover, the moments of GPDs, that is the x integrals of x^nH_q etc., are polynomials in ξ of order n+1. Another important property of GPDs are Ji's sum rules [89]

$$\frac{1}{2} \int_{-1}^{1} dx \ x \left(H_q(x,\xi,t) + E_q(x,\xi,t) \right) = J_q(t), \tag{18.41}$$

where $J_q(0)$ is the total angular momentum carried by quarks and antiquarks of flavour q, with a similar relation for gluons.

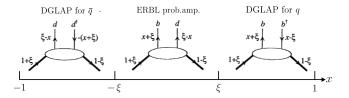

Figure 18.7: Schematic diagrams of the three distinct kinematic regions of (the imaginary part of) H_q . The proton and quark momentum fractions refer to \bar{P}^+ , and x covers the interval (-1,1). In the ERBL domain the GPDs are generalisations of distribution amplitudes which occur in processes such as $p\bar{p} \to J/\psi$.

To visualize the physical content of H_q , we Fourier expand ψ and $\bar{\psi}$ in terms of quark, antiquark creation (b,d) and annihilation $(b^{\dagger},d^{\dagger})$ operators, and sketch the result in Fig. 18.7. There are two types of domain: (i) the time-like or 'annihilation' domain, with $|x|<|\xi|$, where the GPDs describe the wave functions of a t-channel $q\bar{q}$ (or gluon) pair and evolve according to modified ERBL equations [96,97]; (ii) the space-like or 'scattering' domain, with $|x|>|\xi|$, where the GPDs generalise the familiar \bar{q} , q (and gluon) PDFs and describe 'deeply virtual Compton scattering' $(\gamma^*p\to\gamma p), \ \gamma p\to J/\psi p,$ etc., and evolve according to modified DGLAP equations. The splitting functions for the evolution of GPDs are known to NLO [98].

GPDs describe new aspects of proton structure and must be determined from experiment. We can parametrise them in terms of 'double distributions' [99,100], which reduce to diagonal PDFs as $\xi \to 0$. With an additional physically reasonable 'Regge' assumption of no extra singularity at $\xi = 0$, GPDs at low ξ are uniquely given in terms of diagonal PDFs to $O(\xi)$, and have been used [101] to describe $\gamma p \to J/\psi p$ data. Alternatively, flexible SO(3)-based parametrisations have been used to determine GPDs from DVCS data [102].

* The value of $\eta^{\rm CC}$ deduced from Ref. 1 is found to be a factor of two too small; $\eta^{\rm CC}$ of Eq. (18.9) agrees with Refs. [2,3].

NOTE: THE FIGURES IN THIS SECTION ARE INTENDED TO SHOW THE REPRESENTATIVE DATA. THEY ARE NOT MEANT TO BE COMPLETE COMPILATIONS OF ALL THE WORLD'S RELIABLE DATA.

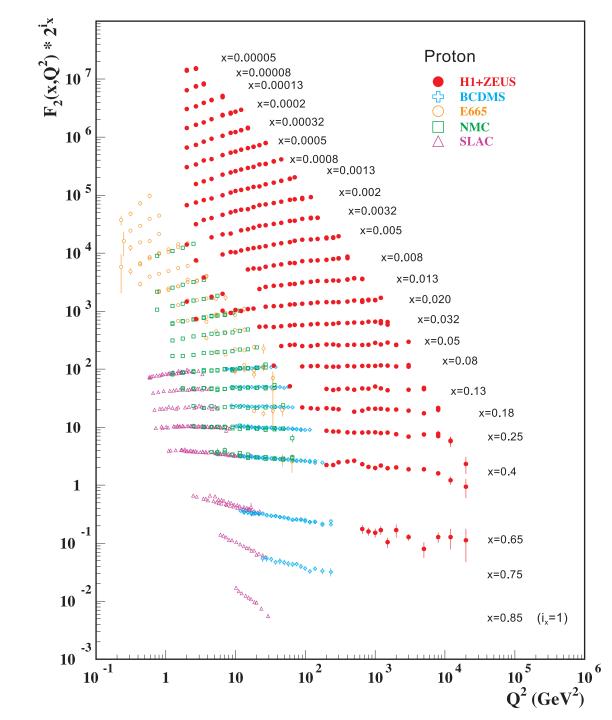

Figure 18.8: The proton structure function F_2^p measured in electromagnetic scattering of electrons and positrons on protons (collider experiments H1 and ZEUS for $Q^2 \ge 2 \text{ GeV}^2$), in the kinematic domain of the HERA data (see Fig. 18.10 for data at smaller x and Q^2), and for electrons (SLAC) and muons (BCDMS, E665, NMC) on a fixed target. Statistical and systematic errors added in quadrature are shown. The data are plotted as a function of Q^2 in bins of fixed x. Some points have been slightly offset in Q^2 for clarity. The H1+ZEUS combined binning in x is used in this plot; all other data are rebinned to the x values of these data. For the purpose of plotting, F_2^p has been multiplied by 2^{ix} , where i_x is the number of the x bin, ranging from $i_x = 1$ (x = 0.85) to $i_x = 24$ (x = 0.00005). References: H1 and ZEUS—F.D. Aaron et al., JHEP 1001, 109 (2010); BCDMS—A.C. Benvenuti et al., Phys. Lett. B223, 485 (1989) (as given in [66]); E665—M.R. Adams et al., Phys. Rev. D54, 3006 (1996); NMC—M. Arneodo et al., Nucl. Phys. B483, 3 (1997); SLAC—L.W. Whitlow et al., Phys. Lett. B282, 475 (1992).

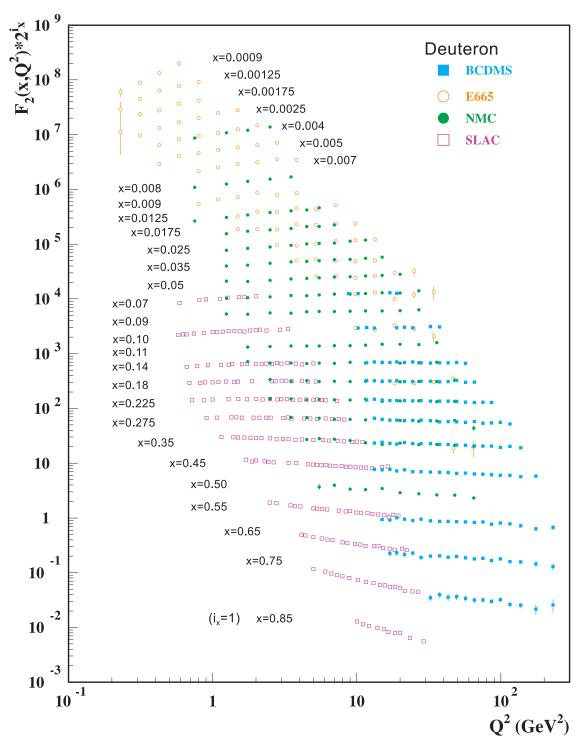

Figure 18.9: The deuteron structure function F_2^d measured in electromagnetic scattering of electrons (SLAC) and muons (BCDMS, E665, NMC) on a fixed target, shown as a function of Q^2 for bins of fixed x. Statistical and systematic errors added in quadrature are shown. For the purpose of plotting, F_2^d has been multiplied by 2^{ix} , where i_x is the number of the x bin, ranging from 1 (x = 0.85) to 29 (x = 0.0009). References: BCDMS—A.C. Benvenuti et al., Phys. Lett. B237, 592 (1990). E665, NMC, SLAC—same references as Fig. 18.8.

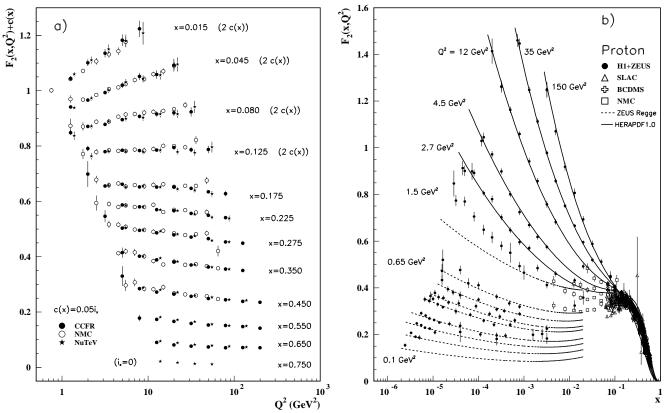

Figure 18.10: a) The deuteron structure function F_2 measured in deep inelastic scattering of muons on a fixed target (NMC) is compared to the structure function F_2 from neutrino-iron scattering (CCFR and NuTeV) using $F_2^{\mu} = (5/18)F_2^{\nu} - x(s+\overline{s})/6$, where heavy-target effects have been taken into account. The data are shown versus Q^2 , for bins of fixed x. The NMC data have been rebinned to CCFR and NuTeV x values. For the purpose of plotting, a constant $c(x) = 0.05i_x$ is added to F_2 , where i_x is the number of the x bin, ranging from 0 (x = 0.75) to 7 (x = 0.175). For $i_x = 8$ (x = 0.125) to 11 (x = 0.015), 2c(x) has been added. References: NMC—M. Arneodo et al., Nucl. Phys. B483, 3 (1997); CCFR/NuTeV—U.K. Yang et al., Phys. Rev. Lett. 86, 2741 (2001); NuTeV—M. Tzanov et al., Phys. Rev. D74, 012008 (2006).

b) The proton structure function F_2^p mostly at small x and Q^2 , measured in electromagnetic scattering of electrons and positrons (H1, ZEUS), electrons (SLAC), and muons (BCDMS, NMC) on protons. Lines are ZEUS Regge and HERAPDF parameterizations for lower and higher Q^2 , respectively. The width of the bins can be up to 10% of the stated Q^2 . Some points have been slightly offset in x for clarity. References: **H1 and ZEUS**—F.D. Aaron *et al.*, JHEP **1001**, 109 (2010) (for both data and HERAPDF parameterization); **ZEUS**—J. Breitweg *et al.*, Phys. Lett. **B487**, 53 (2000) (ZEUS Regge parameterization); **BCDMS**, **NMC**, **SLAC**—same references as Fig. 18.8.

Statistical and systematic errors added in quadrature are shown for both plots.

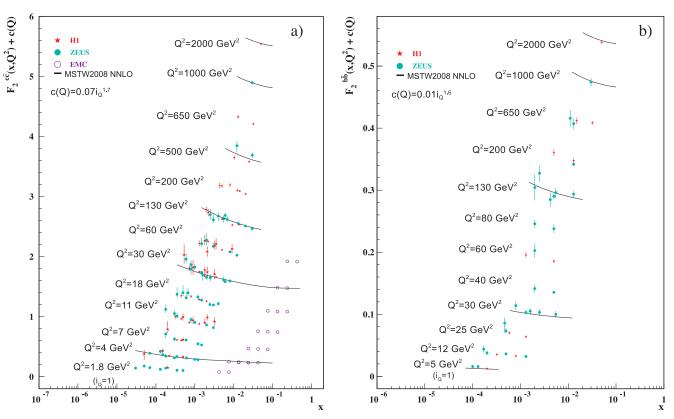

Figure 18.11: a) The charm quark structure function $F_2^{c\overline{c}}(x)$, i.e. that part of the inclusive structure function F_2^p arising from the production of charm quarks, measured in electromagnetic scattering of positrons on protons (H1, ZEUS) and muons on iron (EMC). For the purpose of plotting, a constant $c(Q) = 0.07i_Q^{1.7}$ is added to $F_2^{c\overline{c}}$ where i_Q is the number of the Q^2 bin, ranging from 1 ($Q^2 = 1.8 \text{ GeV}^2$) to 13 ($Q^2 = 2000 \text{ GeV}^2$). References: **ZEUS**—J. Breitweg *et al.*, Eur. Phys. J. **C12**, 35 (2000); S. Chekanov *et al.*, Phys. Rev. **D69**, 012004 (2004); S. Chekanov *et al.*, JHEP **07**, 074 (2007); S. Chekanov *et al.*, Eur. Phys. J. **C65**, 65 (2010); **H1**—C. Adloff *et al.*, Z. Phys. **C72**, 593 (1996); C. Adloff *et al.*, Phys. Lett. **B528**, 199 (2002); F.D. Aaron *et al.*, Phys. Lett. **B686**, 91 (2010); F.D. Aaron *et al.*, Eur. Phys. J. **C65**, 89 (2010); **EMC**—J.J. Aubert *et al.*, Nucl. Phys. **B213**, 31 (1983).

b) The bottom quark structure function $F_2^{b\overline{b}}(x)$. For the purpose of plotting, a constant $c(Q)=0.01i_Q^{1.6}$ is added to $F_2^{b\overline{b}}$ where i_Q is the number of the Q^2 bin, ranging from 1 ($Q^2=5~{\rm GeV^2}$) to 12 ($Q^2=2000~{\rm GeV^2}$). References: **ZEUS**—S. Chekanov *et al.*, Eur. Phys. J. **C65**, 65 (2010); H. Abramowicz *et al.*, Eur. Phys. J. **C69**, 347 (2010); H. Abramowicz *et al.*, Eur. Phys. J. **C71**, 1573 (2010); **H1**—F.D. Aaron *et al.*, Eur. Phys. J. **C65**, 89 (2010).

For both plots, statistical and systematic errors added in quadrature are shown. The data are given as a function of x in bins of Q^2 . Points may have been slightly offset in x for clarity. Some data have been rebinned to common Q^2 values. Also shown is the MSTW2008 parameterization given at several Q^2 values (A.D. Martin *et al.*, Eur. Phys. J. **C63**, 189 (2009)).

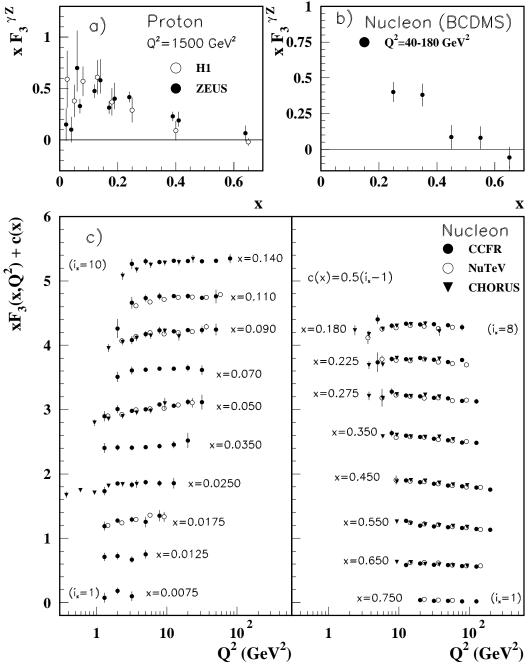

Figure 18.12: The structure function $xF_3^{\gamma Z}$ measured in electroweak scattering of a) electrons on protons (H1 and ZEUS) and b) muons on carbon (BCDMS). The ZEUS points have been slightly offset in x for clarity. References: H1—C. Adloff et~al., Eur. Phys. J. C30, 1 (2003); ZEUS—S. Chekanov et~al., Eur. Phys. J. C28, 175 (2003); S. Chekanov et~al., Eur. Phys. J. C62, 625 (2009); BCDMS—A. Argento et~al., Phys. Lett. B140, 142 (1984).

c) The structure function xF_3 of the nucleon measured in ν -Fe scattering. The data are plotted as a function of Q^2 in bins of fixed x. For the purpose of plotting, a constant $c(x)=0.5(i_x-1)$ is added to xF_3 , where i_x is the number of the x bin as shown in the plot. The NuTeV and CHORUS points have been shifted to the nearest corresponding x bin as given in the plot and slightly offset in Q^2 for clarity. References: CCFR—W.G. Seligman et al., Phys. Rev. Lett. **79**, 1213 (1997); NuTeV—M. Tzanov et al., Phys. Rev. D**74**, 012008 (2006); CHORUS—G. Önengüt et al., Phys. Lett. B**632**, 65 (2006).

Statistical and systematic errors added in quadrature are shown for all plots.

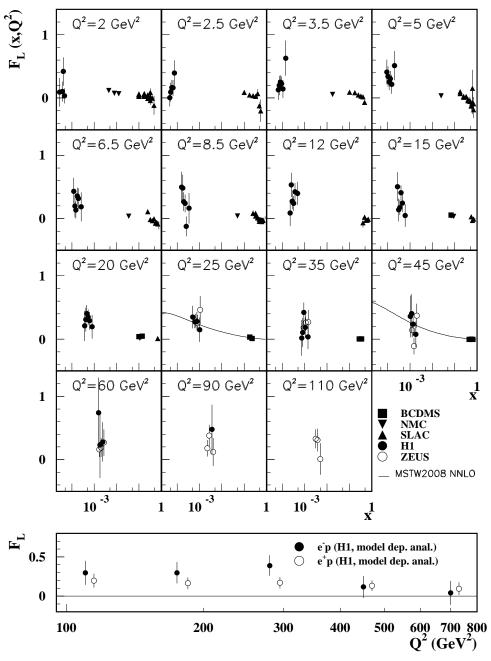

Figure 18.13: Top panel: The longitudinal structure function F_L as a function of x in bins of fixed Q^2 measured on the proton (except for the SLAC data which also contain deuterium data). BCDMS, NMC, and SLAC results are from measurements of R (the ratio of longitudinal to transverse photon absorption cross sections) which are converted to F_L by using the BDCMS parameterization of F_2 (A.C. Benvenuti et al., Phys. Lett. B223, 485 (1989)). It is assumed that the Q^2 dependence of the fixed-target data is small within a given Q^2 bin. Some of the other data may have been rebinned to common Q^2 values. Also shown is the MSTW2008 parameterization given at two Q^2 values (A.D. Martin et al., Eur. Phys. J. C63, 189 (2009)). References: H1—F.D. Aaron et al., Phys. Lett. B665, 139 (2008); F.D. Aaron et al., Eur. Phys. J. C71, 1579 (2011); ZEUS—S. Chekanov et al., Phys. Lett. B682, 8 (2009); BCDMS—A. Benvenuti et al., Phys. Lett. B223, 485 (1989); NMC—M. Arneodo et al., Nucl. Phys. B483, 3 (1997); SLAC—L.W. Whitlow et al., Phys. Lett. B250, 193 (1990) and numerical values from the thesis of L.W. Whitlow (SLAC-357).

Bottom panel: Higher Q^2 values of the longitudinal structure function F_L as a function of Q^2 given at the measured x for e^+/e^- -proton scattering. Points have been slightly offset in Q^2 for clarity. References: **H1**—C. Adloff $et\ al.$, Eur. Phys. J. **C30**, 1 (2003).

The H1 results shown in the bottom plot require the assumption of the validity of the QCD form for the F_2 structure function in order to extract F_L . Statistical and systematic errors added in quadrature are shown for both plots.

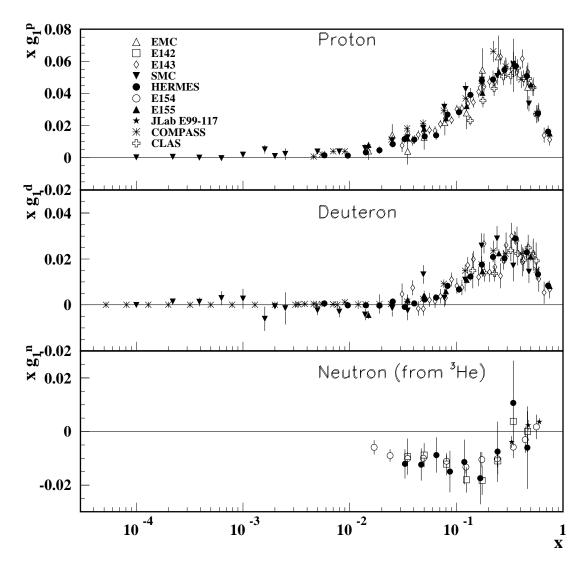

Figure 18.14: The spin-dependent structure function $xg_1(x)$ of the proton, deuteron, and neutron (from 3 He target) measured in deep inelastic scattering of polarized electrons/positrons: E142 ($Q^2 \sim 0.3-10~{\rm GeV}^2$), E143 ($Q^2 \sim 0.3-10~{\rm GeV}^2$), E154 ($Q^2 \sim 1-17~{\rm GeV}^2$), E155 ($Q^2 \sim 1-40~{\rm GeV}^2$), JLab E99-117 ($Q^2 \sim 2.71-4.83~{\rm GeV}^2$), HERMES ($Q^2 \sim 0.18-20~{\rm GeV}^2$), CLAS ($Q^2 \sim 1-5~{\rm GeV}^2$) and muons: EMC ($Q^2 \sim 1.5-100~{\rm GeV}^2$), SMC ($Q^2 \sim 0.01-100~{\rm GeV}^2$), COMPASS ($Q^2 \sim 0.001-100~{\rm GeV}^2$), shown at the measured Q^2 (except for EMC data given at $Q^2=10.7~{\rm GeV}^2$ and E155 data given at $Q^2=5~{\rm GeV}^2$). Note that $g_1^n(x)$ may also be extracted by taking the difference between $g_1^d(x)$ and $g_1^p(x)$, but these values have been omitted in the bottom plot for clarity. Statistical and systematic errors added in quadrature are shown. References: EMC—J. Ashman *et al.*, Nucl. Phys. B328, 1 (1989); E142—P.L. Anthony *et al.*, Phys. Rev. D54, 6620 (1996); E143—K. Abe *et al.*, Phys. Rev. D58, 112003 (1998); SMC—B. Adeva *et al.*, Phys. Rev. D58, 112001 (1998), B. Adeva *et al.*, Phys. Rev. D60, 072004 (1999) and Erratum-Phys. Rev. D62, 079902 (2000); HERMES—A. Airapetian *et al.*, Phys. Rev. D75, 012007 (2007) and K. Ackerstaff *et al.*, Phys. Lett. B404, 383 (1997); E154—K. Abe *et al.*, Phys. Rev. C70, 065207 (2004); COMPASS—V.Yu. Alexakhin *et al.*, Phys. Lett. B647, 8 (2007), E.S. Ageev *et al.*, Phys. Lett. B647, 330 (2007), and M.G. Alekseev *et al.*, Phys. Lett. B690, 466 (2010); CLAS—K.V. Dharmawardane *et al.*, Phys. Lett. B641, 11 (2006) (which also includes resonance region data not shown on this plot).

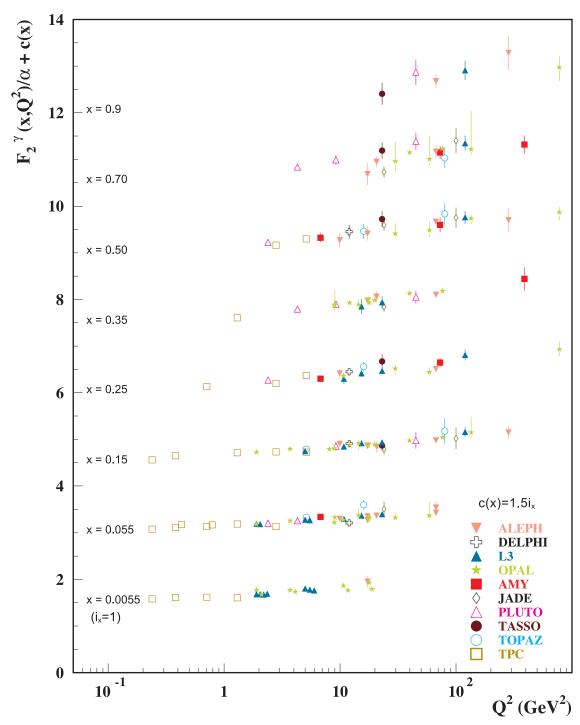

Figure 18.15: The hadronic structure function of the photon F_2^{γ} divided by the fine structure constant α measured in e^+e^- scattering, shown as a function of Q^2 for bins of x. Data points have been shifted to the nearest corresponding x bin as given in the plot. Some points have been offset in Q^2 for clarity. Statistical and systematic errors added in quadrature are shown. For the purpose of plotting, a constant $c(x)=1.5i_x$ is added to F_2^{γ}/α where i_x is the number of the x bin, ranging from 1 (x=0.0055) to 8 (x=0.9). References: ALEPH-R. Barate et al., Phys. 19. FRAGMENTATION FUNCTIONS IN e^+e^- , ep AND pp COLLISIONS

Revised August 2011 by O. Biebel (Ludwig-Maximilians-Universität, Munich, Germany), D. de Florian (Dep. de Física, FCEyN-UBA, Buenos Aires, Argentina), D. Milstead (Fysikum, Stockholms Universitet, Sweden), and A. Vogt (Dep. of Mathematical Sciences, University of Liverpool, UK).

19.1. Introduction to fragmentation

The term 'fragmentation functions' is widely used for two related if conceptually different sets of functions describing final-state single particle energy distributions in hard scattering processes (see Refs. [1,2] for introductory reviews, and Refs. [3,4] for summaries of recent experimental and theoretical research in this field).

The first are cross-section observables such as the functions $F_{T,L,A}(x,s)$ in semi-inclusive e^+e^- annihilation at center-of-mass (CM) energy \sqrt{s} via an intermediate photon or Z-boson, $e^+e^- \rightarrow \gamma/Z \rightarrow h+X$, given by

$$\frac{1}{\sigma_0} \frac{d^2 \sigma^h}{dx \, d\cos \theta} = \frac{3}{8} (1 + \cos^2 \theta) F_T^h + \frac{3}{4} \sin^2 \theta \, F_L^h + \frac{3}{4} \cos \theta \, F_A^h \, . \tag{19.1}$$

Here $x=2E_h/\sqrt{s}\leq 1$ is the scaled energy of the hadron h (in practice the approximation $x\simeq x_p=2p_h/\sqrt{s}$ is often used), and θ is its angle relative to the electron beam in the CM frame. Eq. (19.1) is the most general form for unpolarized inclusive single-particle production via vector bosons [5]. The transverse and longitudinal fragmentation functions F_T and F_L represent the contributions from γ/Z polarizations transverse or longitudinal with respect to the direction of motion of the hadron. The parity-violating term with the asymmetric fragmentation function F_A arises from the interference between vector and axial-vector contributions. Normalization factors σ_0 used in the literature range from the total cross section $\sigma_{\rm tot}$ for $e^+e^- \to {\rm hadrons}$, including all weak and QCD contributions, to $\sigma_0 = 4\pi\alpha^2N_c/3s$ with $N_c=3$, the lowest-order QED cross section for $e^+e^- \to \mu^+\mu^-$ times the number of colors N_c . LEP1 measurements of all three fragmentation functions are shown in Fig. 19.1.

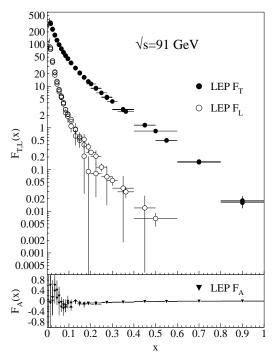

Figure 19.1: LEP1 measurements of total transverse (F_T) , longitudinal (F_L) , and asymmetric (F_A) fragmentation functions [6–8]. Data points with relative errors greater than 100% are omitted.

Integration of Eq. (19.1) over θ yields the total fragmentation function $F^h = F_T^h + F_L^h$,

$$\frac{1}{\sigma_0} \frac{d\sigma^h}{dx} = F^h(x, s) = \sum_i \int_x^1 \frac{dz}{z} C_i(z, \alpha_s(\mu), \frac{s}{\mu^2}) D_i^h(\frac{x}{z}, \mu^2) + \mathcal{O}(\frac{1}{\sqrt{s}})$$
(19.2)

with $i=u,\,\bar{u},\,d,\,\bar{d},\,\ldots,\,g$. Here we have introduced the second set of functions mentioned in the first paragraph, the parton fragmentation functions (or fragmentation densities) D_i^h . These functions are the final-state analogue of the initial-state parton distributions addressed in Section 18 of this *Review*. Due to the different sign of the squared four-momentum q^2 of the intermediate gauge boson these two sets of distributions are also referred to as the timelike $(e^+e^-$ annihilation, $q^2>0$) and spacelike (deep-inelastic scattering (DIS), $q^2<0$) parton distributions. The function $D_i^h(z,\mu^2)$ encodes the

probability that the parton i fragments into a hadron h carrying a fraction z of the parton's momentum. Beyond the leading order (LO) of perturbative QCD these universal functions are factorization-scheme dependent, with 'reasonable' scheme choices retaining certain quark-parton-model (QPM) constraints such as the momentum sum rule

$$\sum_{i} \int_{0}^{1} dz \, z \, D_{i}^{h}(z, \mu^{2}) \, = \, 1 \, . \tag{19.3}$$

The dependence of the functions D_i^h on the factorization (or fragmentation) scale μ^2 (in Eq. (19.2) and below identified with the renormalization scale) is discussed in Section 19.2.

The second ingredient in Eq. (19.2), and analogous expressions for the functions $F_{T,L,A}$, are the observable-dependent coefficient functions C_i . At the zeroth order in the strong coupling $\alpha_{\rm S}$ the coefficient functions C_g for gluons are zero, while for (anti-) quarks $C_i = g_i(s) \, \delta(1-z)$ except for F_L , where $g_i(s)$ is the appropriate electroweak coupling. In particular, $g_i(s)$ is proportional to the squared charge of the quark i at $s \ll M_Z^2$, when weak effects can be neglected. The full electroweak prefactors $g_i(s)$ can be found in Ref. [5]. The power corrections in Eq. (19.2) arise from quark and hadron mass terms and from non-perturbative effects.

Measurements of fragmentation in lepton-hadron and hadron-hadron scattering are complementary to those in e^+e^- annihilation. The latter provides a clean environment (no initial-state hadron remnant) and stringent constraints on the combinations $D_{q_i}^h + D_{\bar{q}_i}^h$. However e^+e^- annihilation is far less sensitive to D_g^h and insensitive to the charge asymmetries $D_{q_i}^h - D_{\bar{q}_i}^h$. These quantities are best constrained in proton–(anti-)proton and electron-proton scattering, respectively. Especially the latter provides a more complicated environment with which it is possible to study the influence on the fragmentation process from initial state QCD radiation, the partonic and spin structure of the hadron target, and the target remnant system (see Ref. [9] for a comprehensive review of the measurements and models of fragmentation in lepton-hadron scattering).

Moreover, unlike e^+e^- annihilation where $q^2=s$ is fixed by the collider energy, lepton-hadron scattering has two independent scales, $Q^2=-q^2$ and the invariant mass W^2 of the hadronic final state, which both can vary by several orders of magnitudes for a given CM energy, thus allowing the study of fragmentation in different environments by a single experiment. E.g., in photoproduction the exchanged photon is quasi-real $(Q^2\approx 0)$ leading to processes akin to hadron-hadron scattering. In DIS $(Q^2\gg 1~{\rm GeV}^2)$, using the QPM, the hadronic fragments of the struck quark can be directly compared with quark fragmentation in e^+e^- in a suitable frame. Results from lepton-hadron experiments quoted in this report primarily concern fragmentation in the DIS regime. Studies performed by lepton-hadron experiments of fragmentation with photoproduction data containing high transverse momentum jets or particles are also reported, when these are directly comparable to DIS and e^+e^- results.

Fragmentation studies at HERA are usually performed in one of two frames in which the target hadron and the exchanged boson are collinear. The hadronic center-of-mass frame (HCMS) is defined as the rest system of the exchanged boson and incoming hadron, with the z^* -axis defined along the direction of the exchanged boson. The positive z^* direction defines the so-called current region. Fragmentation measurements performed in the HCMS often use the Feynman-x variable $x_F=2p_z^*/W,$ where p_z^* is the longitudinal momentum of the particle in this frame. As W is the invariant mass of the hadronic final state, x_F ranges between -1 and 1.

The Breit system [10] is connected to the HCMS by a longitudinal boost such that the time component of q vanishes, i.e, q=(0,0,0,-Q). In the QPM, the struck parton then has the longitudinal momentum Q/2 which becomes -Q/2 after the collision. As compared with the HCMS, the current region of the Breit frame is more closely matched to the partonic scattering process, and is thus appropriate for direct comparisons of fragmentation functions in DIS with those from e^+e^- annihilation. The variable $x_p=2p^*/Q$ is used at HERA for measurements in the Breit frame, ensuring rather directly comparable DIS and e^+e^- results, where p^* is the particle's momentum in the current region of the Breit frame.

19.2. Scaling violation

The simplest parton-model approach would predict scale-independent x-distributions ('scaling') for both the fragmentation function F^h and the parton fragmentation functions D^h_i . Perturbative QCD corrections lead, after factorization of the final-state collinear singularities for light partons, to logarithmic scaling violations via the evolution equations

$$\frac{\partial}{\partial \ln \mu^2} D_i(x, \mu^2) = \sum_j \int_x^1 \frac{dz}{z} P_{ji}(z, \alpha_s(\mu^2)) D_j(\frac{x}{z}, \mu^2) . \tag{19.4}$$

Usually this system of equations is decomposed into a 2×2 flavour-singlet sector comprising gluon and the sum of all quark and antiquark fragmentation functions, and scalar ('non-singlet') equations for quark-antiquark and flavour differences. Notice that the singlet splitting-function matrix is now P_{ji} , rather than P_{ij} as for the initial-state parton distributions, since D_j represents the fragmentation of the final parton.

The splitting functions in Eq. (19.4) have perturbative expansion of

$$P_{ji}(z,\alpha_{\rm s}) = \frac{\alpha_{\rm s}}{2\pi} P_{ji}^{(0)}(z) + \left(\frac{\alpha_{\rm s}}{2\pi}\right)^2 P_{ji}^{(1)}(z) + \left(\frac{\alpha_{\rm s}}{2\pi}\right)^3 P_{ji}^{(2)}(z) + \dots (19.5)$$

where the leading-order (LO) functions $P^{(0)}(z)$ [11,12] are the same as those for the initial-state parton distributions. The next-to-leading order (NLO) corrections $P^{(1)}(z)$ have been calculated in Refs. [13–17] (there are well-known misprints in the journal version of Ref. [14]). Ref. [17] also includes the spin-dependent case. These functions are different from, but related to their space-like counterparts, see also Ref. [18]. These relations have facilitated recent calculations of the next-to-next-to-leading order (NNLO) quantities $P_{qq}^{(2)}(z)$ and $P_{gg}^{(2)}(z)$ in Eq. (19.5) [19,20]. The corresponding off-diagonal quantities $P_{qg}^{(2)}$ and $P_{gq}^{(2)}$ were recently obtained in Ref. [21] by using similar relations supplemented with constrains from the momentum sum rule Eq. (19.3) [20] and the supersymmetric limit. An uncertainty, which does not affect the logarithmic behaviour at small and large momentum fractions, still remains on the $P_{qg}^{(2)}$ kernel. All these results refer to the standard $\overline{\rm MS}$ scheme, with the exception of Refs. [16], with a fixed number $n_{\it f}$ of light flavours. The NLO treatment of flavour thresholds in the evolution has been addressed in Ref. [22].

The QCD parts of the coefficient functions for $F_{T,L,A}(x,s)$ in Eq. (19.1) and the total fragmentation function $F_2^h \equiv F^h$ in Eq. (19.2) are given by

$$C_{a,i}(z,\alpha_{\rm S}) = (1 - \delta_{aL}) \, \delta_{iq} + \frac{\alpha_{\rm S}}{2\pi} \, c_{a,i}^{(1)}(z) + \left(\frac{\alpha_{\rm S}}{2\pi}\right)^2 c_{a,i}^{(2)}(z) + \dots$$
 (19.6)

The first-order corrections have been calculated a long time ago in Refs. [23], and the second-order terms in [24]. The latter results have recently been verified (and some typos corrected) in Refs. [19,25]. Thus the coefficient functions are known to NNLO except for F_L where the leading contribution is of order α_8 .

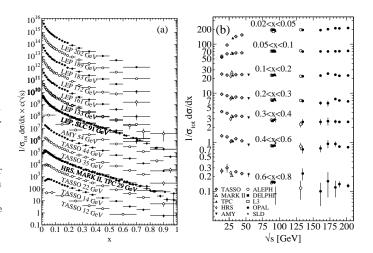

Figure 19.2: The e^+e^- fragmentation function for all charged particles is shown [8, 26–42] (a) for different CM energies \sqrt{s} versus x and (b) for various ranges of x versus \sqrt{s} . For the purpose of plotting (a), the distributions were scaled by $c(\sqrt{s}) = 10^i$ with i ranging from i = 0 ($\sqrt{s} = 12$ GeV) to i = 13 ($\sqrt{s} = 202$ GeV).

The effect of the evolution is similar in the timelike and spacelike cases: as the scale increases, one observes a scaling violation in which the x-distribution is shifted towards lower values. This can be seen from Fig. 19.2 where a large amount of measurements of the total fragmentation function in e^+e^- annihilation are summarized. QCD analyses of these data are discussed in Section 19.5 below.

Unlike the splitting functions in Eq. (19.5), see Refs. [18–20], the coefficient functions for $F_{2,T,A}$ in Eq. (19.6) show a threshold enhancement with terms up to $\alpha_s^{\ n}(1-z)^{-1}\ln^{2n-1}(1-z)$. Such logarithms can be resummed to all orders in α_s using standard soft-gluon techniques [43–45]. Recently this resummation has been extended to the subleading (and for F_L leading) class $\alpha_s^{\ n} \ln^k(1-z)$ of large-x logarithms [46,47].

In Refs. [23] the NLO coefficient functions have been calculated also for single hadron production in lepton-proton scattering, $ep \rightarrow e + h + X$. More recently corresponding results have been obtained for the case that a non-vanishing transverse momentum is required in the HCMS frame [48].

Scaling violations in DIS are shown in Fig. 19.3 for both HCMS and Breit frame. In Fig. 1.3(a) the distribution in terms of $x_F = 2p_z^*/W$ shows a steeper slope in ep data than for the lower-energy μp data for $x_F > 0.15$, indicating the scaling violations. At smaller values of x_F in the current jet region, the multiplicity of particles substantially increases with W owing to the increased phase space available for the fragmentation process. The EMC data access both the current region and the region of the fragmenting target remnant system. At higher values of $|x_F|$, due to the extended nature of the remnant, the multiplicity in the target region far exceeds that in the current region. For acceptance reasons the remnant hemisphere of the HCMS is only accessible by the lower-energy fixed-target experiments.

Using hadrons from the current hemisphere in the Breit frame, measurements of fragmentation functions and the production properties of particles in ep scattering have been made by Refs. [53–58]. Fig. 19.3(b) compares results from ep scattering and e^+e^- experiments, the latter results are halved as they cover both event hemispheres. The agreement between the DIS and e^+e^- results is fairly good. However, processes in DIS which are not present in e^+e^- annihilation, such as boson-gluon fusion and initial state QCD radiation, can depopulate the current region. These effects become most prominent at low values of Q and x_p . Hence, when compared with e^+e^- annihilation data at $\sqrt{s}=5.2$, 6.5 GeV [60] not shown here, the DIS particle rates tend to lie below those from e^+e^- annihilation. A recent ZEUS study [61] finds that the direct comparability of the ep data to e^+e^- results at low scales is improved if twice the energy in the current hemisphere of

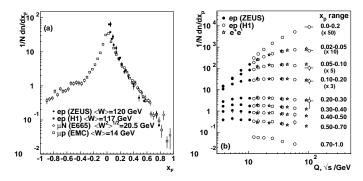

Figure 19.3: (a) The distribution $1/N \cdot dN/dx_F$ for all charged particles in DIS lepton-hadron experiments at different values of W, and measured in the HCMS [49–52]. (b) Scaling violations of the fragmentation function for all charged particles in the current region of the Breit frame of DIS [53,58] and in e^+e^- interactions [41,59]. The data are shown as a function of \sqrt{s} for e^+e^- results, and as a function of Q for the DIS results, each within the same indicated intervals of the scaled momentum x_P . The data for the four lowest intervals of x_P are multiplied by factors 50, 10, 5, and 3, respectively for clarity.

the Breit frame, $2E_R^{\rm cr}$, is used instead of Q as the fragmentation scale.

19.3. Fragmentation functions for small particle momenta

The higher-order timelike splitting functions in Eq. (19.5) are very singular at small x. They show a double-logarithmic (LL) enhancement with leading terms of the form $\alpha_s^n \ln^{2n-2} x$ corresponding to poles $\alpha_s^n (N-1)^{1-2n}$ for the Mellin moments

$$P^{(n)}(N) = \int_0^1 dx \ x^{N-1} \ P^{(n)}(x) \ . \tag{19.7}$$

Despite large cancellations between leading and non-leading logarithms at non-asymptotic value of x, the resulting small-x rise in the timelike splitting functions dwarfs that of their spacelike counterparts for the evolution of the parton distributions in Section 18 of this Review, see Fig. 1 of Ref. [20]. Consequently the fixed-order approximation to the evolution breaks down orders of magnitude in x earlier in fragmentation than in DIS.

The pattern of the known coefficients and other considerations suggest that the LL terms sum to all-order expressions without any pole at N=1 such as [62,63]

$$P_{gg}^{\rm LL}(N) = -\frac{1}{4}(N - 1 - \sqrt{(N - 1)^2 \cdot 24 \,\alpha_{\rm s}/\pi})$$
 (19.8)

Keeping the first three terms in the resulting expansion of Eq. (19.4) around N=1 yields a Gaussian in the variable $\xi=\ln(1/x)$ for the small-x fragmentation functions,

$$xD(x,s) \propto \exp\left[-\frac{1}{2\sigma^2}(\xi - \xi_p)^2\right],$$
 (19.9)

with the peak position and width varying with the energy as [64] (see also Ref. [2])

$$\xi_p \simeq \frac{1}{4} \ln \left(\frac{s}{\Lambda^2} \right) , \quad \sigma \propto \left[\ln \left(\frac{s}{\Lambda^2} \right) \right]^{3/4} .$$
 (19.10)

Next-to-leading order corrections to the above predictions have been calculated [65]. In the method of Ref. [66], see also Refs. [67,68], the corrections are included in an analytical form known as the 'modified leading logarithmic approximation' (MLLA). Alternatively they can be used to compute higher-moment corrections to the shape in Eq. (19.9) [69]. Double-logarithmic contributions to the gluonic coefficient were derived in the standard $\overline{\rm MS}$ scheme in Ref. [70]. The resummation of the dominant small x terms for the flavour-singlet splitting kernels and coefficient functions was recently studied in [71].

Fig. 19.4 shows the ξ distribution for charged particles produced in the current region of the Breit frame in DIS and in e^+e^- annihilation. Consistent with Eq. (19.9) (the 'hump backed plateau') and Eq. (19.10) the distributions have a Gaussian shape with the peak position and area increasing with the CM energy (e^+e^-) and Q^2 (DIS).

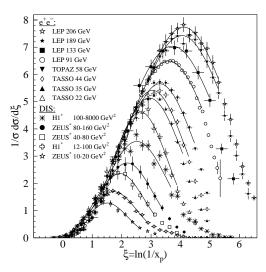

Figure 19.4: Distribution of $\xi = \ln(1/x_p)$ at several CM energies (e⁺e⁻) [26–28,33–36,41,72–75] and intervals of Q^2 (DIS) [56,57]. At each energy only one representative measurement is displayed. For clarity some measurements at intermediate CM energies (e⁺e⁻) or Q^2 ranges (DIS) are not shown. The DIS measurements (*) have been scaled by a factor of 2 for direct comparability with the e^+e^- results. Fits of simple Gaussian functions are overlaid for illustration.

The predicted energy dependence Eq. (19.10) of the peak in the ξ distribution is explained by soft gluon coherence (angular ordering) which correctly predicts the suppression of hadron production at small x. Of course, a decrease at very small x is expected on purely kinematical grounds, but this would occur at particle energies proportional to their masses, i.e., at $x \propto m/\sqrt{s}$ and hence $\xi \sim \frac{1}{2} \ln s$. Thus, if the suppression were purely kinematic, the peak position ξ_p would vary twice as rapidly with the energy, which is ruled out by the data in Fig. 19.5. The e⁺e⁻ and DIS data agree well with each other, demonstrating the universality of hadronization, and the MLLA prediction. Measurements of the higher moments of the ξ distribution in e^+e^- [41,75–77] and DIS [57] have also been performed and show consistency with each other.

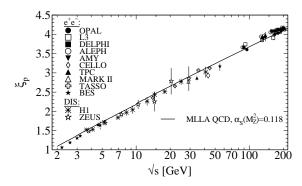

Figure 19.5: Evolution of the peak position, ξ_p , of the ξ distribution with the CM energy \sqrt{s} . The MLLA QCD prediction using $\alpha_S(s=M_Z^2)=0.118$ is superimposed to the data of Refs. [26,28,29,32–34,36,41,55,56,73,74,77–85].

19.4. Fragmentation models

Although the scaling violation can be calculated perturbatively, the actual form of the parton fragmentation functions is non-perturbative. Perturbative evolution gives rise to a shower of quarks and gluons (partons). Multi-parton final states from leading and higher order matrix element calculations are linked to these parton showers using factorization prescriptions, also called matching schemes, see Ref. [86] for an overview. Phenomenological schemes are then used to model the carry-over of parton momenta and flavor to the hadrons. Two of the very popular models are the string fragmentation [87,88], implemented in the JETSET [89], PYTHIA [90] and UCLA [91] Monte Carlo event generation programs, and the cluster fragmentation of the HERWIG [92] and SHERPA [93] Monte Carlo event generators. For details see Chap. 38 of this Review.

19.5. Quark and gluon fragmentation functions

The fragmentation functions are solutions to the evolution equations Eq. (19.4), but need to be parametrized at some initial scale μ_0^2 (usually around 1 GeV² for light quarks and gluons and m_Q^2 for heavy quarks). A usual parametrization for light hadrons is [94–100]

$$D_i^h(x,\mu_0^2) = N x^\alpha (1-x)^\beta \left(1 + \gamma (1-x)^\delta\right) \; , \eqno(19.11)$$

where the normalization N, and the parameters α , β , γ and δ in general depend on the energy scale μ_0^2 , and also on the type of the parton, i, and the hadron, h. Frequently the term involving γ and δ is left out [96–99]. Heavy flavor fragmentation into heavy mesons is discussed in Sec. 19.9. The parameters of Eq. (19.11) (see [94–99]) are obtained by performing global fits to data on various hadron types for different combinations of partons and hadrons in e^+e^- , lepton-hadron and hadron-hadron collisions.

Data from e^+e^- annihilation present the cleanest experimental source for the measurement of fragmentation functions, but can not contribute to disentangle quark from antiquark distributions. Since the bulk of the e^+e^- annihilation data is obtained at the mass of the Z-boson, where the electroweak couplings are roughly the same for the different partons, it provides the most precise determination of the flavor-singlet quark fragmentation. Flavor tagged results [101], distinguishing between the light quark, charm and bottom contributions are of particular value for flavor decomposition, even though those measurements can not be unambiguously interpreted in perturbative QCD.

The most relevant source for quark-antiquark (and also flavor) separation is provided by data from semi-inclusive DIS (SIDIS). Semi-inclusive measurements are usually performed at much lower scales than for e^+e^- annihilation. The inclusion of SIDIS data in global fits allows for a wider coverage in the evolution of the fragmentation functions, resulting at the same time in a stringent test of the universality of these distributions. Charged-hadron production data in hadronic collisions also presents a sensitivity on (anti-)quark fragmentation functions.

The gluon fragmentation function $D_g(x)$ can be extracted, in principle, from the longitudinal fragmentation function F_L in Eq. (19.2), as the coefficient functions $C_{L,i}$ for quarks and gluons are comparable at order α_s . However at NLO, i.e., including the $\mathcal{O}(\alpha_s^2)$ coefficient functions $C_{L,i}^{(2)}$ [24], quark fragmentation is dominant in F_L over a large part of the kinematic range, reducing the sensitivity on D_g . This distribution could be determined also analyzing the evolution of the fragmentation functions. This possibility is limited by the lack of sufficiently precise data at energy scales away from the Z-resonance and the dominance of the quark contributions and at medium and large values of x.

 D_g can also be deduced from the fragmentation of three-jet events in which the gluon jet is identified, for example, by tagging the other two jets with heavy quark decays. To leading order, the measured distributions of $x=E_{\rm had}/E_{\rm jet}$ for particles in gluon jets can be identified directly with the gluon fragmentation functions $D_g(x)$. At higher orders the theoretical interpretation of this observable is ambiguous.

A direct constraint on D_g is provided by $pp, p\bar{p} \to hX$ data. At variance with e^+e^- annihilation and SIDIS, for this process gluon fragmentation starts to contribute at the lowest order in the coupling constant, introducing a strong sensitivity on D_g . At large $x \gtrsim 0.5$, where information from e^+e^- is sparse, data from hadronic colliders facilitate significantly improved extractions of D_g [94,95].

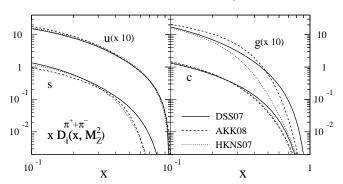

Figure 19.6: Comparison of up, strange, charm and gluon NLO fragmentation functions for $\pi^+ + \pi^-$ at the mass of the Z. The different lines correspond to the result of the most recent analyses performed in Refs. [94,95,99].

A comparison of recent fits of NLO fragmentation functions for $\pi^+ + \pi^-$ obtained by DSS07 [94], AKK08 [95] and HKNS07 [99] is shown in Fig. 19.6. Differences between the sets are large especially for the gluon fragmentation function over the full range of x and for the quark distribution at large momentum fractions. Those discrepancies can be considered as a first estimate of the present uncertainties involved in the extraction of the fragmentation functions. The differences are even larger for other species of hadrons like kaons and protons [94,95,99].

19.6. Identified particles in e^+e^- and semi-inclusive DIS

A great wealth of measurements of e^+e^- fragmentation into identified particles exists. A collection of references for data on fragmentation into identified particles is given on Table 46.1. Representative of this body of data is Fig. 19.7 which shows fragmentation functions as the scaled momentum spectra of charged particles at several CM energies.

Quantitative results of studies of scaling violation in e^+e^- fragmentation have been reported in [6,39,103,104]. The values of α_s obtained are consistent with the world average (see review on QCD in Section 9 of this Review).

Many studies have been made of identified particles produced in lepton-hadron scattering, although fewer particle species have been measured than in e^+e^- collisions. References [105–110] and [111–117] are representative of the data from fixed target and ep collider experiments, respectively.

QCD calculations performed at NLO provide an overall good description of the HERA data [52,53,57,112,118,119] for both SIDIS [120] and the hadron transverse momentum distribution [48] in the kinematic regions in which the calculations are predictive.

Fig. 19.8(a) compares lower-energy fixed-target and HERA data on strangeness production, showing that the HERA spectra have substantially increased multiplicities, albeit with insufficient statistical precision to study scaling violations. The fixed-target data show that the Λ rate substantially exceeds the $\overline{\Lambda}$ rate in the remnant region, owing to the conserved baryon number from the baryon target. Fig. 19.8(b) shows neutral and charged pion fragmentation functions $1/N \cdot dn/dz$, where z is defined as the ratio of the pion energy to that of the exchanged boson, both measured in the laboratory frame. Results are shown from HERMES and the EMC experiments, where HERMES data have been evolved with NLO QCD to $\langle Q^2 \rangle = 25~{\rm GeV^2}$ in order to be consistent with the EMC. Each of the experiments uses various kinematic cuts to ensure that the measured particles lie in

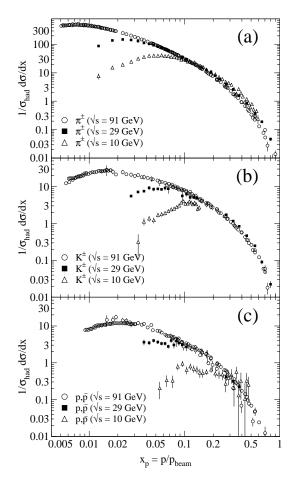

Figure 19.7: Scaled momentum spectra of (a) π^{\pm} , (b) K^{\pm} , and (c) p/\overline{p} at $\sqrt{s}=10, 29,$ and 91 GeV [38,42,82,102].

the region which is expected to be associated with the struck quark. In the DIS kinematic regime accessed at these experiments, and over the range in z shown in Fig. 19.8, the z and x_F variables have similar values [49]. The precision data on identified particles can be used in the study of the quark flavor content of the proton [121].

Data on identified particle production can aid the investigation of the universality of jet fragmentation in e^+e^- and DIS. The strangeness suppression factor γ_s , as derived principally from tuning the Lund string model [88] within JETSET [89], is typically found to be around 0.3 in e^+e^- experiments [72], although values closer to 0.2 [122] have also been obtained. A number of measurements of so-called V^0 -particles (K^0, Λ^0) and the relative rates of V^0 's and inclusively produced charged particles have been performed at HERA [111,113,117] and fixed target experiments [105]. These typically favour a stronger suppression $(\gamma_s \approx 0.2)$ than usually obtained from e^+e^- data although values close to 0.3 have also been obtained [123,124].

However, when comparing the description of QCD-based models for lepton-hadron interactions and e^+e^- collisions, it is important to note that the overall description by event generators of inclusively produced hadronic final states is more accurate in e^+e^- collisions than lepton-hadron interactions [125]. Predictions of particle rates in lepton-hadron scattering are affected by uncertainties in the modelling of the parton composition of the proton and photon, the extended target remnant, and initial and final state QCD radiation. Furthermore, the tuning of event generators for e^+e^- collisions is typically based on a larger set of parameters and uses more observables [72] than are used when optimizing models for lepton-hadron data [126].

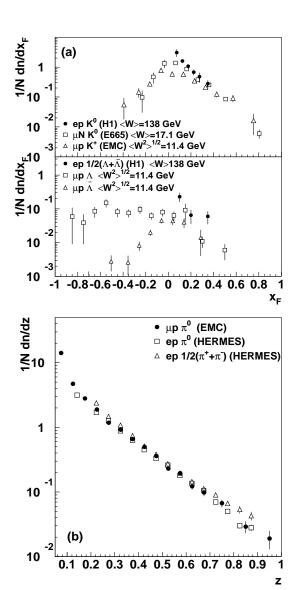

Figure 19.8: (a) $1/N \cdot dn/dx_F$ for identified strange particles in DIS at various values of W [105,108,111]. (b) $1/N \cdot dn/dz$ for measurements of pions from fixed-target DIS experiment [106,109,110].

19.7. Fragmentation in hadron-hadron collisions

An extensive set on high-transverse momentum (p_T) single-inclusive hadron data has been collected in $h_1h_2 \to hX$ scattering processes, both at high energy colliders and fixed-target experiments [127–145]. Only the transverse momentum p_T is considered in hadron-hadron collisions because of lack of knowledge of the longitudinal momentum of the hard subprocess. Fig. 19.9 shows a compilation of neutral pion and charged hadron production data for energies in the range $\sqrt{s}\approx 23$ - 800 GeV.

The differential cross-section for high-transverse momentum distributions has been computed to next-to-leading order accuracy in perturbative QCD [146]. NLO calculations yield a good description of the collider data, but significantly under-predict the cross-section for several fixed-target energy data sets [147,148]. Data collected at high energy colliders are either included in global fit analyses or used as a test for the universality of fragmentation functions.

Different strategies have been developed to a meliorate the theoretical description at fixed-target energies. A possible phenomenological approach involves the introduction of a non-perturbative in trinsic partonic transverse momentum [145,149,150]. From the perturbative side, the resummation of the dominant higher order corrections at

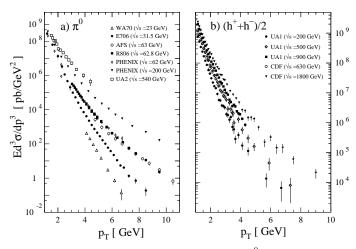

Figure 19.9: Selection of inclusive (a) π^0 and (b) charged-hadron production data from pp [135,142–145] and $p\bar{p}$ [127,130,133] collisions.

threshold produces an enhancement of the theoretical calculation that significantly improves the description of the data [151,152].

Measurements of hadron production in longitudinally polarized pp collisions are used mainly in the determination of the polarized gluon distribution in the proton [153,154].

Hadron production provides a critical observable for probing the high energy-density matter produced in heavy-ion collisions. Measurements at colliders show a suppression of inclusive hadron yields at high transverse momentum for AA collisions compared to pp scattering, indicating the formation of a dense medium opaque to quark and gluons, see e.g. [155].

19.8. Spin-dependent fragmentation

Measurements of charged-hadron production in unpolarized leptonhadron scattering provide a unique tool to perform a flavor-separation determination of polarized parton densities from DIS interactions with longitudinally polarized targets [156–160].

Polarized scattering presents the possibility to measure the spin transfer from the struck quark to the final hadron, and thus develop spin-dependent fragmentation functions [161,162]. Early measurements of the longitudinal spin transfer to Lambda hyperons have been presented in [163,164]. This process is also useful in the study of the quark transversity distribution [165], which describes the probability of finding a transversely polarized quark with its spin aligned or anti-aligned with the spin of a transversely polarized nucleon. The transversity function is chiral-odd, and therefore not accessible through measurements of inclusive lepton-hadron scattering. Semi-inclusive DIS, in which another chiral-odd observable may be involved, provides a valuable tool to probe transversity. The Collins fragmentation function [166] relates the transverse polarization of the quark to that of the final hadron. It is chiral-odd and naive T-odd, leading to a characteristic single spin asymmetry in the azimuthal angular distribution of the produced hadron in the hadron scattering plane. Azimuthal angular distributions in semi-inclusive DIS can also be produced by other processes requiring non-polarized fragmentation functions, like the Sivers mechanism [167].

A number of experiments have measured these asymmetries [168–178]. Collins and Sivers asymmetries have been shown experimentally to be non zero by the HERMES measurements on transversely polarized proton targets [169–171]. Independent information on the Collins function has been provided by the BELLE Collaboration [172–173]. Measurements performed by the COMPASS collaboration on deuteron targets show results compatible with zero for both asymmetries [174–176].

19.9. Heavy quark fragmentation

It was recognized very early [179] that a heavy flavored meson should retain a large fraction of the momentum of the primordial heavy quark, and therefore its fragmentation function should be much harder than that of a light hadron. In the limit of a very heavy quark, one expects the fragmentation function for a heavy quark to go into any heavy hadron to be peaked near x=1.

When the heavy quark is produced at a momentum much larger than its mass, one expects important perturbative effects, enhanced by powers of the logarithm of the transverse momentum over the heavy quark mass, to intervene and modify the shape of the fragmentation function. In leading logarithmic order (i.e., including all powers of $\alpha_{\rm s}\log m_{\rm Q}/p_T$), the total (i.e., summed over all hadron types) perturbative fragmentation function is simply obtained by solving the leading evolution equation for fragmentation functions, Eq. (19.4), with the initial condition at a scale $\mu^2=m_{\rm Q}^2$ given by $D_{\rm Q}(z,m_{\rm Q}^2)=\delta(1-z)$ and $D_i(z,m_{\rm Q}^2)=0$ for $i\neq {\rm Q}$ (here $D_i(z)$, stands for the probability to produce a heavy quark Q from parton i with a fraction z of the parton momentum).

Several extensions of the leading logarithmic result have appeared in the literature. Next-to-leading-log (NLL) order results for the perturbative heavy quark fragmentation function have been obtained in [180]. The resummation of the dominant logarithmic contributions at large z was performed in [43] to next-to-leading-log accuracy. Fixed-order calculations of the fragmentation function at order $\alpha_{\rm s}^2$ in e^+e^- annihilation have appeared in [181] while the initial condition for the perturbative heavy quark fragmentation function has been extended to NNLO in [182].

Inclusion of non-perturbative effects in the calculation of the heavy-quark fragmentation function is done by convoluting the perturbative result with a phenomenological non-perturbative form [183–188], see also section 17.8 of [189]. The parameters entering the non-perturbative forms are fitted together with some model of hard radiation, which can be either a shower Monte Carlo, a leading-log or NLL calculation (which may or may not include Sudakov resummation), or a fixed order calculation [181,190].

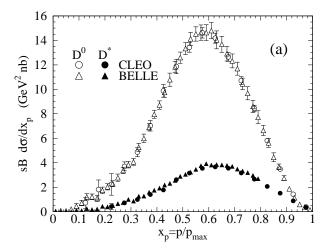

A more conventional approach [191] involves the introduction of a unique set of heavy quark fragmentation functions of non-perturbative nature that obey the usual massless evolution equations in Eq. (19.4). Finite mass terms of the form $(m_{\rm Q}/p_T)^n$ are kept in the corresponding short distance coefficient function for each scattering process. Within this approach, the initial condition for the perturbative fragmentation function provides the term needed to define the correct subtraction scheme to match the massless limit for the coefficient function (see e.g. [192]) . Such implementation is in line with the variable flavor number scheme introduced for parton distributions functions, as described in Section 18 of this Review.

High statistics data for charmed mesons production near the Υ resonance (excluding decay products of B mesons) have been published [193,194]. They include results for D and D^* , D_s (see also [195,196]) and Λ_c . Shown in Fig. 19.10(a) are the CLEO and BELLE inclusive cross-sections times branching ratio \mathcal{B} , $s \cdot \mathcal{B} d\sigma/dx_p$, for the production of D^0 and D^{*+} . The variable x_p approximates the light-cone momentum fraction z, but is not identical to it. The two measurements are consistent with each other.

The branching ratio \mathcal{B} represents $D^0 \to K^-\pi^+$ for the D^0 results and for the D^{*+} the product branching fraction: $D^{*+} \to D^0\pi^+$, $D^0 \to K^-\pi^+$. Given the high precision of CLEO's and BELLE's data, a superposition of different parametric forms for the non-perturbative contribution is needed to obtain a good fit [22]. Older studies are reported in Refs. [197–199]. Charmed meson spectra on the Z peak have been published by OPAL and ALEPH [200,201].

Charm quark production has also been extensively studied at HERA by the H1 and ZEUS collaborations. Measurements have been made of $D^{*\pm}$, D^{\pm} , and D_s^{\pm} mesons; see, for example, Refs. [202,203]. The production of the Λ_c baryon has also been studied [204].

Experimental studies of the fragmentation function for b quarks, shown in Fig. 19.10(b), have been performed at LEP and SLD [205–207]. Commonly used methods identify the B meson

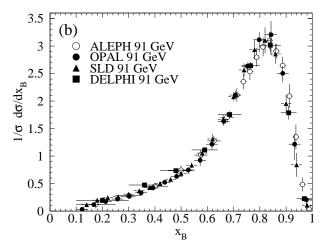

Figure 19.10: (a) Efficiency-corrected inclusive cross-section measurements for the production of D^0 and D^{*+} in e^+e^- measurements at $\sqrt{s}\approx 10.6$ GeV, excluding B decay products [193,194]. (b) Measured e^+e^- fragmentation function of b quarks into B hadrons at $\sqrt{s}\approx 91$ GeV [206].

through its semileptonic decay or based upon tracks emerging from the B secondary vertex. The studies in [206] fit the B spectrum using a Monte Carlo shower model supplemented with non-perturbative fragmentation functions yielding consistent results.

The experiments measure primarily the spectrum of B mesons. This defines a fragmentation function which includes the effect of the decay of higher mass excitations, like the B^* and B^{**} . In the literature, there is sometimes ambiguity in what is defined to be the bottom fragmentation function. Instead of using what is directly measured (i.e., the B meson spectrum) corrections are applied to account for B^* or B^{**} production in some cases. For a more detailed discussion see section 17.8 of [189].

Heavy-flavor production in e^+e^- collisions is the primary source of information for the role of fragmentation effects in heavy-flavor production in hadron-hadron and lepton-hadron collisions. The QCD calculations tend to underestimate the data in certain regions of phase space. The discrepancy observed between theoretical calculations and the measured B meson spectrum at the hadron colliders [208] is substantially reduced when a more refined use of information on heavy flavor production from e^+e^- data is made [209] and when up-to-date parton distributions and strong coupling constant values are considered [210].

Both bottomed- and charmed-mesons spectra have been measured at the Tevatron with unprecedented accuracy [211]. The measured spectra are in good agreement with QCD calculations (including non-perturbative fragmentation effects inferred from $\mathrm{e^+e^-}$ data [212]),

no longer supporting the previously reported discrepancies [208].

The HERA collaborations have produced a number of measurements of beauty production; see, for example, Refs. [202,213–215]. As for the Tevatron data, the HERA results are described well by QCD-based calculations using fragmentation models optimised with $\rm e^+e^-$ data.

Besides degrading the fragmentation function by gluon radiation, QCD evolution can also generate soft heavy quarks, increasing in the small x region as \sqrt{s} increases. Several theoretical studies are available on the issue of how often $b\bar{b}$ or $c\bar{c}$ pairs are produced indirectly, via a gluon splitting mechanism [216–218]. Experimental results from studies on charm and bottom production via gluon splitting, given in [201,219–223], yield weighted averages of $\overline{n}_{g\to c\overline{c}}=3.05\pm0.45\%$ and $\overline{n}_{g\to b\overline{b}}=0.277\pm0.072\%$, respectively.

20. EXPERIMENTAL TESTS OF GRAVITATIONAL THEORY

Revised October 2011 by T. Damour (IHES, Bures-sur-Yvette, France).

Einstein's General Relativity, the current "standard" theory of gravitation, describes gravity as a universal deformation of the Minkowski metric:

$$g_{\mu\nu}(x^{\lambda}) = \eta_{\mu\nu} + h_{\mu\nu}(x^{\lambda})$$
, where $\eta_{\mu\nu} = \text{diag}(-1, +1, +1, +1)$. (20.1)

General Relativity is classically defined by two postulates. One postulate states that the Lagrangian density describing the propagation and self-interaction of the gravitational field is

$$\mathcal{L}_{\rm Ein}[g_{\mu\nu}] = \frac{c^4}{16\pi G_N} \sqrt{g} g^{\mu\nu} R_{\mu\nu}(g) , \qquad (20.2)$$

$$R_{\mu\nu}(g) = \partial_{\alpha}\Gamma^{\alpha}_{\mu\nu} - \partial_{\nu}\Gamma^{\alpha}_{\mu\alpha} + \Gamma^{\beta}_{\alpha\beta}\Gamma^{\alpha}_{\mu\nu} - \Gamma^{\beta}_{\alpha\nu}\Gamma^{\alpha}_{\mu\beta} , \qquad (20.3)$$

$$\Gamma^{\lambda}_{\mu\nu} = \frac{1}{2}g^{\lambda\sigma}(\partial_{\mu}g_{\nu\sigma} + \partial_{\nu}g_{\mu\sigma} - \partial_{\sigma}g_{\mu\nu}) , \qquad (20.4)$$

where G_N is Newton's constant, $g = -\det(g_{\mu\nu})$, and $g^{\mu\nu}$ is the matrix inverse of $g_{\mu\nu}$. A second postulate states that $g_{\mu\nu}$ couples universally, and minimally, to all the fields of the Standard Model by replacing everywhere the Minkowski metric $\eta_{\mu\nu}$. Schematically (suppressing matrix indices and labels for the various gauge fields and fermions and for the Higgs doublet),

$$\mathcal{L}_{SM}[\psi, A_{\mu}, H, g_{\mu\nu}] = -\frac{1}{4} \sum \sqrt{g} g^{\mu\alpha} g^{\nu\beta} F^{a}_{\mu\nu} F^{a}_{\alpha\beta}$$

$$- \sum \sqrt{g} \overline{\psi} \gamma^{\mu} D_{\mu} \psi$$

$$- \frac{1}{2} \sqrt{g} g^{\mu\nu} \overline{D_{\mu} H} D_{\nu} H - \sqrt{g} V(H)$$

$$- \sum \lambda \sqrt{g} \overline{\psi} H \psi , \qquad (20.5)$$

where $\gamma^{\mu}\gamma^{\nu} + \gamma^{\nu}\gamma^{\mu} = 2g^{\mu\nu}$, and where the covariant derivative D_{μ} contains, besides the usual gauge field terms, a spin-dependent gravitational contribution. From the total action follow Einstein's field equations,

$$R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} = \frac{8\pi G_N}{c^4} T_{\mu\nu} \ . \tag{20.6}$$

Here $R=g^{\mu\nu}R_{\mu\nu}$, $T_{\mu\nu}=g_{\mu\alpha}g_{\nu\beta}T^{\alpha\beta}$, and $T^{\mu\nu}=(2/\sqrt{g})\delta \mathcal{L}_{\rm SM}/\delta g_{\mu\nu}$ is the (symmetric) energy-momentum tensor of the Standard Model matter. The theory is invariant under arbitrary coordinate transformations: $x'^{\mu}=f^{\mu}(x^{\nu})$. To solve the field equations Eq. (20.6), one needs to fix this coordinate gauge freedom. E.g., the "harmonic gauge" (which is the analogue of the Lorenz gauge, $\partial_{\mu}A^{\mu}=0$, in electromagnetism) corresponds to imposing the condition $\partial_{\nu}(\sqrt{g}g^{\mu\nu})=0$.

In this Review, we only consider the classical limit of gravitation (i.e. classical matter and classical gravity). Considering quantum matter in a classical gravitational background already poses interesting challenges, notably the possibility that the zero-point fluctuations of the matter fields generate a nonvanishing vacuum energy density $\rho_{\rm vac}$, corresponding to a term $-\sqrt{g}~\rho_{\rm vac}$ in $\mathcal{L}_{\rm SM}$ [1]. This is equivalent to adding a "cosmological constant" term $+\Lambda~g_{\mu\nu}$ on the left-hand side of Einstein's equations Eq. (20.6), with $\Lambda = 8\pi G_N~\rho_{\rm vac}/c^4$. Recent cosmological observations (see the following Reviews) suggest a positive value of Λ corresponding to $\rho_{\rm vac} \approx (2.3 \times 10^{-3} {\rm eV})^4$. Such a small value has a negligible effect on the tests discussed below.

20.1. Experimental tests of the coupling between matter and gravity

The universality of the coupling between $g_{\mu\nu}$ and the Standard Model matter postulated in Eq. (20.5) ("Equivalence Principle") has many observable consequences [2,3]. First, it predicts that the outcome of a local non-gravitational experiment, referred to local standards, does not depend on where, when, and in which locally inertial frame, the experiment is performed. This means, for instance, that local experiments should neither feel the cosmological evolution of the universe (constancy of the "constants"), nor exhibit preferred directions in spacetime (isotropy of space, local Lorentz

invariance). These predictions are consistent with many experiments and observations. Stringent limits on a possible time variation of the basic coupling constants have been obtained by analyzing a natural fission reactor phenomenon which took place at Oklo, Gabon, two billion years ago [4,5]. These limits are at the 1×10^{-7} level for the fractional variation of the fine-structure constant $\alpha_{\rm em}$ [5], and at the 4×10^{-9} level for the fractional variation of the ratio between the light quark masses and Λ_{QCD} [6]. The determination of the lifetime of Rhenium 187 from isotopic measurements of some meteorites dating back to the formation of the solar system (about 4.6 Gyr ago) yields comparably strong limits [7]. Measurements of absorption lines in astronomical spectra also give stringent limits on the variability of both $\alpha_{\rm em}$ (at the 10^{-5} level [8]) , and $\mu=m_p/m_e$, e.g.

$$|\Delta\mu/\mu| < 1.8 \times 10^{-6} (95\% \ C.L.)$$
, (20.7)

at a redshift z=0.68466 [9], and $\Delta\mu/\mu=(0.3\pm3.2_{\rm stat}\pm1.9_{\rm sys})\times10^{-6}$ at the large redshift z=2.811 [10]. Direct laboratory limits on the (present) time variation of $\alpha_{\rm em}$ (based on monitoring the frequency ratio of several different atomic clocks) have recently reached the level [11]:

$$\dot{\alpha}_{\rm em}/\alpha_{\rm em} = (-1.6 \pm 2.3) \times 10^{-17} {\rm yr}^{-1}.$$

There are also experimental limits on a possible dependence of coupling constants on the gravitational potential [12]. See [13] for a review of the issue of "variable constants."

The highest precision tests of the isotropy of space have been performed by looking for possible quadrupolar shifts of nuclear energy levels [14]. The (null) results can be interpreted as testing the fact that the various pieces in the matter Lagrangian Eq. (20.5) are indeed coupled to one and the same external metric $g_{\mu\nu}$ to the 10^{-29} level. For astrophysical constraints on possible Planck-scale violations of Lorentz invariance, see Ref. 15.

The universal coupling to $g_{\mu\nu}$ postulated in Eq. (20.5) implies that two (electrically neutral) test bodies dropped at the same location and with the same velocity in an external gravitational field fall in the same way, independently of their masses and compositions. The universality of the acceleration of free fall has been verified at the 10^{-13} level for laboratory bodies, notably Beryllium and Titanium test bodies [16],

$$(\Delta a/a)_{\text{BeTi}} = (0.3 \pm 1.8) \times 10^{-13} ,$$
 (20.8)

as well as for the gravitational accelerations of the Earth and the Moon toward the Sun [17],

$$(\Delta a/a)_{\text{EarthMoon}} = (-1.0 \pm 1.4) \times 10^{-13}$$
. (20.9)

The latter result constrains not only how $g_{\mu\nu}$ couples to matter, but also how it couples to itself [18]("strong equivalence principle"; see Eq. (20.15) below, and the end of the section on binary pulsar tests). See also Ref. 19 for a review of torsion balance experiments.

Finally, Eq. (20.5) also implies that two identically constructed clocks located at two different positions in a static external Newtonian potential $U(\boldsymbol{x}) = \sum G_N m/r$ exhibit, when intercompared by means of electromagnetic signals, the (apparent) difference in clock rate, $\tau_1/\tau_2 = \nu_2/\nu_1 = 1 + [U(\boldsymbol{x}_1) - U(\boldsymbol{x}_2)]/c^2 + O(1/c^4)$, independently of their nature and constitution. This universal gravitational redshift of clock rates has been verified at the 10^{-4} level by comparing a hydrogen-maser clock flying on a rocket up to an altitude $\sim 10,000$ km to a similar clock on the ground [20]. The redshift due to a height change of only 33 cm has been recently detected by comparing two optical clocks based on $^{27}\text{Al}^+$ ions [21].

20.2. Tests of the dynamics of the gravitational field in the weak field regime

The effect on matter of one-graviton exchange, *i.e.*, the interaction Lagrangian obtained when solving Einstein's field equations Eq. (20.6) written in, say, the harmonic gauge at first order in $h_{\mu\nu}$,

$$\Box h_{\mu\nu} = -\frac{16\pi G_N}{c^4} (T_{\mu\nu} - \frac{1}{2} T \eta_{\mu\nu}) + O(h^2) + O(hT) , \qquad (20.10)$$

reads $-(8\pi G_N/c^4)T^{\mu\nu}\Box^{-1}(T_{\mu\nu}-\frac{1}{2}T\eta_{\mu\nu})$. For a system of N moving point masses, with free Lagrangian $L^{(1)}=\sum_{A=1}^N-m_Ac^2\sqrt{1-v_A^2/c^2}$, this interaction, expanded to order v^2/c^2 , reads (with $r_{AB}\equiv |x_A-x_B|$, $n_{AB}\equiv (x_A-x_B)/r_{AB}$)

$$L^{(2)} = \frac{1}{2} \sum_{A \neq B} \frac{G_N m_A m_B}{r_{AB}} \left[1 + \frac{3}{2c^2} (\mathbf{v}_A^2 + \mathbf{v}_B^2) - \frac{7}{2c^2} (\mathbf{v}_A \cdot \mathbf{v}_B) - \frac{1}{2c^2} (\mathbf{n}_{AB} \cdot \mathbf{v}_A) (\mathbf{n}_{AB} \cdot \mathbf{v}_B) + O\left(\frac{1}{c^4}\right) \right].$$
(20.11)

The two-body interactions, Eq. (20.11), exhibit v^2/c^2 corrections to Newton's 1/r potential induced by spin-2 exchange ("gravito-magnetism"). Consistency at the "post-Newtonian" level $v^2/c^2 \sim G_N \, m/rc^2$ requires that one also considers the three-body interactions induced by some of the three-graviton vertices and other nonlinearities (terms $O(h^2)$ and O(hT) in Eq. (20.10)),

$$L^{(3)} = -\frac{1}{2} \sum_{B \neq A \neq C} \frac{G_N^2 m_A m_B m_C}{r_{AB} r_{AC} c^2} + O\left(\frac{1}{c^4}\right) . \tag{20.12}$$

All currently performed gravitational experiments in the solar system, including perihelion advances of planetary orbits, the bending and delay of electromagnetic signals passing near the Sun, and very accurate ranging data to the Moon obtained by laser echoes, are compatible with the post-Newtonian results Eqs. (20.10)-(20.12). The "gravito-magnetic" interactions $\propto v_A v_B$ contained in Eq. (20.11) are involved in many of these experimental tests. They have been particularly tested in lunar laser ranging data [17], in the LAGEOS satellite observations [22], and in the dedicated Gravity Probe B mission [23].

Similar to what is done in discussions of precision electroweak experiments, it is useful to quantify the significance of precision gravitational experiments by parameterizing plausible deviations from General Relativity. The addition of a mass-term in Einstein's field equations leads to a score of theoretical difficulties which have not yet received any consensual solution. We shall, therefore, not consider here the ill-defined "mass of the graviton" as a possible deviation parameter from General Relativity (see, however, Ref. 24). Deviations from Einstein's pure spin-2 theory are then defined by adding new, bosonic light or massless, macroscopically coupled fields. The possibility of new gravitational-strength couplings leading (on small, and possibly large, scales) to deviations from Einsteinian (and Newtonian) gravity is suggested by String Theory [25], and by Brane World ideas [26]. For reviews of experimental constraints on Yukawatype additional interactions, see Refs. [19,27]. Recent experiments have set limits on non-Newtonian forces below 0.056 mm [28].

Here, we shall focus on the parametrization of long-range deviations from relativistic gravity obtained by adding a strictly massless (i.e. without self-interaction $V(\varphi)=0$) scalar field φ coupled to the trace of the energy-momentum tensor $T=g_{\mu\nu}T^{\mu\nu}$ [29]. The most general such theory contains an arbitrary function $a(\varphi)$ of the scalar field, and can be defined by the Lagrangian

$$\mathcal{L}_{\text{tot}}[g_{\mu\nu}, \varphi, \psi, A_{\mu}, H] = \frac{c^4}{16\pi G} \sqrt{g} (R(g_{\mu\nu}) - 2g^{\mu\nu} \partial_{\mu} \varphi \partial_{\nu} \varphi) + \mathcal{L}_{\text{SM}}[\psi, A_{\mu}, H, \tilde{g}_{\mu\nu}] , \qquad (20.13)$$

where G is a "bare" Newton constant, and where the Standard Model matter is coupled not to the "Einstein" (pure spin-2) metric $g_{\mu\nu}$, but to the conformally related ("Jordan-Fierz") metric $\widetilde{g}_{\mu\nu}=\exp(2a(\varphi))g_{\mu\nu}$. The scalar field equation $\Box_g\varphi=-(4\pi G/c^4)\alpha(\varphi)T$ displays $\alpha(\varphi)\equiv\partial a(\varphi)/\partial\varphi$ as the basic (field-dependent) coupling between φ and matter [30]. The one-parameter (ω) Jordan-Fierz-Brans-Dicke theory [29] is the special case $a(\varphi)=\alpha_0\varphi$ leading to a field-independent coupling $\alpha(\varphi)=\alpha_0$ (with $\alpha_0^2=1/(2\omega+3)$). The addition of a self-interaction term $V(\varphi)$ in Eq. (20.13) introduces new phenomenological possibilities; notably the "chameleon mechanism" [31].

In the weak-field slow-motion limit appropriate to describing gravitational experiments in the solar system, the addition of φ modifies Einstein's predictions only through the appearance of two "post-Einstein" dimensionless parameters: $\overline{\gamma} = -2\alpha_0^2/(1+\alpha_0^2)$ and $\overline{\beta} =$ $+\frac{1}{2}\beta_0\alpha_0^2/(1+\alpha_0^2)^2$, where $\alpha_0 \equiv \alpha(\varphi_0)$, $\beta_0 \equiv \partial\alpha(\varphi_0)/\partial\varphi_0$, φ_0 denoting the vacuum expectation value of φ . These parameters show up also naturally (in the form $\gamma_{PPN} = 1 + \overline{\gamma}$, $\beta_{PPN} = 1 + \overline{\beta}$) in phenomenological discussions of possible deviations from General Relativity [2]. The parameter $\overline{\gamma}$ measures the admixture of spin 0 to Einstein's graviton, and contributes an extra term $+\overline{\gamma}(v_A-v_B)^2/c^2$ in the square brackets of the two-body Lagrangian Eq. (20.11). The parameter $\overline{\beta}$ modifies the three-body interaction Eq. (20.12) by an overall multiplicative factor $1 + 2\overline{\beta}$. Moreover, the combination $\eta \equiv 4\overline{\beta} - \overline{\gamma}$ parameterizes the lowest order effect of the self-gravity of orbiting masses by modifying the Newtonian interaction energy terms in Eq. (20.11) into $G_{AB}m_Am_B/r_{AB}$, with a body-dependent gravitational "constant" $G_{AB}=G_N[1+\eta(E_A^{\rm grav}/m_Ac^2+E_B^{\rm grav}/m_Bc^2)+O(1/c^4)]$, where $G_N=G\exp[2a(\varphi_0)](1+\alpha_0^2)$ and where $E_A^{\rm grav}$ denotes the gravitational binding energy of body A.

The best current limits on the post-Einstein parameters $\overline{\gamma}$ and $\overline{\beta}$ are (at the 68% confidence level):

$$\overline{\gamma} = (2.1 \pm 2.3) \times 10^{-5} ,$$
 (20.14)

deduced from the additional Doppler shift experienced by radio-wave beams connecting the Earth to the Cassini spacecraft when they passed near the Sun [32], and

$$4\overline{\beta} - \overline{\gamma} = (4.4 \pm 4.5) \times 10^{-4}$$
, (20.15)

from Lunar Laser Ranging measurements [17] of a possible polarization of the Moon toward the Sun [18]. More stringent limits on $\overline{\gamma}$ are obtained in models (e.g., string-inspired ones [25]) where scalar couplings violate the Equivalence Principle.

20.3. Tests of the dynamics of the gravitational field in the radiative and/or strong field regimes

The discovery of pulsars (i.e., rotating neutron stars emitting a beam of radio noise) in gravitationally bound orbits [33,34] has opened up an entirely new testing ground for relativistic gravity, giving us an experimental handle on the regime of radiative and/or strong gravitational fields. In these systems, the finite velocity of propagation of the gravitational interaction between the pulsar and its companion generates damping-like terms at order $(v/c)^5$ in the equations of motion [35]. These damping forces are the local counterparts of the gravitational radiation emitted at infinity by the system ("gravitational radiation reaction"). They cause the binary orbit to shrink and its orbital period P_b to decrease. The remarkable stability of pulsar clocks has allowed one to measure the corresponding very small orbital period decay $\dot{P}_b \equiv dP_b/dt \sim -(v/c)^5 \sim -10^{-12}$ in several binary systems, thereby giving us a direct experimental confirmation of the propagation properties of the gravitational field, and, in particular, an experimental confirmation that the speed of propagation of gravity is equal to the velocity of light to better than a part in a thousand. In addition, the surface gravitational potential of a neutron star $h_{00}(R) \simeq 2Gm/c^2R \simeq 0.4$ being a factor $\sim 10^8$ higher than the surface potential of the Earth, and a mere factor 2.5 below the black hole limit $(h_{00}(R) = 1)$, pulsar data have allowed one to obtain several accurate tests of the strong-gravitational-field regime, as we discuss next.

Binary pulsar timing data record the times of arrival of successive electromagnetic pulses emitted by a pulsar orbiting around the center of mass of a binary system. After correcting for the Earth motion around the Sun and for the dispersion due to propagation in the interstellar plasma, the time of arrival of the Nth pulse t_N can be described by a generic, parameterized "timing formula" [36] whose functional form is common to the whole class of tensor-scalar gravitation theories:

$$t_N - t_0 = F[T_N(\nu_p, \dot{\nu}_p, \ddot{\nu}_p); \{p^K\}; \{p^{PK}\}].$$
 (20.16)

Here, T_N is the pulsar proper time corresponding to the Nth turn given by $N/2\pi = \nu_p T_N + \frac{1}{2}\dot{\nu}_p T_N^2 + \frac{1}{6}\ddot{\nu}_p T_N^3$ (with $\nu_p \equiv 1/P_p$ the spin frequency of the pulsar, etc.), $\{p^K\} = \{P_b, T_0, e, \omega_0, x\}$ is the set of "Keplerian" parameters (notably, orbital period P_b , eccentricity e, periastron longitude ω_0 and projected semi-major axis $x = a \sin i/c$), and $\{p^{PK}\} = \{k, \gamma_{\text{timing}}, \dot{P}_b, r, s, \delta_\theta, \dot{e}, \dot{x}\}$ denotes the set of (separately measurable) "post-Keplerian" parameters. Most important among these are: the fractional periastron advance per orbit $k \equiv \dot{\omega} P_b/2\pi$, a dimensionful time-dilation parameter γ_{timing} , the orbital period derivative \dot{P}_b , and the "range" and "shape" parameters of the gravitational time delay caused by the companion, r and s.

Without assuming any specific theory of gravity, one can phenomenologically analyze the data from any binary pulsar by least-squares fitting the observed sequence of pulse arrival times to the timing formula Eq. (20.16). This fit yields the "measured" values of the parameters $\{\nu_p, \dot{\nu}_p, \ddot{\nu}_p\}$, $\{p^K\}$, $\{p^{FK}\}$. Now, each specific relativistic theory of gravity predicts that, for instance, k, $\gamma_{\text{timing}}, \dot{P}_b$, r and s (to quote parameters that have been successfully measured from some binary pulsar data) are some theory-dependent functions of the Keplerian parameters and of the (unknown) masses m_1 , m_2 of the pulsar and its companion. For instance, in General Relativity, one finds (with $M \equiv m_1 + m_2$, $n \equiv 2\pi/P_b$)

$$\begin{split} k^{\text{GR}}(m_1, m_2) = & 3(1 - e^2)^{-1} (G_N M n/c^3)^{2/3} , \\ \gamma^{\text{GR}}_{\text{timing}}(m_1, m_2) = & en^{-1} (G_N M n/c^3)^{2/3} m_2 (m_1 + 2m_2)/M^2 , \\ \dot{P}_b^{\text{GR}}(m_1, m_2) = & - (192\pi/5)(1 - e^2)^{-7/2} \left(1 + \frac{73}{24}e^2 + \frac{37}{96}e^4\right) \\ & \times (G_N M n/c^3)^{5/3} m_1 m_2/M^2 , \\ r(m_1, m_2) = & G_N m_2/c^3 , \\ s(m_1, m_2) = & nx(G_N M n/c^3)^{-1/3} M/m_2 . \end{split}$$
(20.17)

In tensor-scalar theories, each of the functions $k^{\mathrm{theory}}(m_1, m_2)$, $\gamma_{\mathrm{timing}}^{\mathrm{theory}}(m_1, m_2)$, $\dot{P}_b^{\mathrm{theory}}(m_1, m_2)$, etc., is modified by quasi-static strong field effects (associated with the self-gravities of the pulsar and its companion), while the particular function $\dot{P}_b^{\mathrm{theory}}(m_1, m_2)$ is further modified by radiative effects (associated with the spin 0 propagator) [30,37,38].

Let us give some highlights of the current experimental situation (see Ref. 39 for a more extensive review). In the first discovered binary pulsar PSR1913 + 16 [33,34], it has been possible to measure with accuracy three post-Keplerian parameters: k, $\gamma_{\rm timing}$ and \dot{P}_b . The three equations $k^{\rm measured} = k^{\rm theory}(m_1, m_2)$, $\dot{P}_{\rm timing}^{\rm measured} = \gamma_{\rm timing}^{\rm theory}(m_1, m_2)$, $\dot{P}_b^{\rm measured} = \dot{P}_b^{\rm theory}(m_1, m_2)$ determine, for each given theory, three curves in the two-dimensional mass plane. This yields one (combined radiative/strong-field) test of the specified theory, according to whether the three curves meet at one point, as they should. After subtracting a small ($\sim 10^{-14}$ level in $\dot{P}_b^{\rm obs} = (-2.423 \pm 0.001) \times 10^{-12}$), but significant, Newtonian perturbing effect caused by the Galaxy [40], one finds that General Relativity passes this $(k - \gamma_{\rm timing} - \dot{P}_b)_{1913+16}$ test with complete success at the 10^{-3} level [34,41,42]

$$\[\frac{\dot{P}_b^{\text{obs}} - \dot{P}_b^{\text{galactic}}}{\dot{P}_b^{\text{GR}}[k^{\text{obs}}, \gamma_{\text{timing}}^{\text{obs}}]} \right]_{1913 + 16} = 0.997 \pm 0.002 \ . \tag{20.18}$$

Here $\dot{P}_b^{\rm GR}[k^{\rm obs}, \gamma_{\rm timing}^{\rm obs}]$ is the result of inserting in $\dot{P}_b^{\rm GR}(m_1, m_2)$ the values of the masses predicted by the two equations $k^{\rm obs} =$

 $k^{\mathrm{GR}}(m_1,m_2),~\gamma_{\mathrm{timing}}^{\mathrm{obs}}=\gamma_{\mathrm{timing}}^{\mathrm{GR}}(m_1,m_2).$ This yields experimental evidence for the reality of gravitational radiation damping forces at the $(-3\pm2)\times10^{-3}$ level.

The discovery of the binary pulsar PSR1534 + 12 [43] has allowed one to measure five post-Keplerian parameters: k, $\gamma_{\rm timing}$, r, s, and (with less accuracy) \dot{P}_b [44,45]. This allows one to obtain three (five observables minus two masses) tests of relativistic gravity. Two among these tests probe strong field gravity, without mixing of radiative effects [44]. General Relativity passes all these tests within the measurement accuracy. The most precise of the new, pure strong-field tests is the one obtained by combining the measurements of k, γ , and s. Using the most recent data [45], one finds agreement at the 1% level:

$$\left[\frac{s^{\text{obs}}}{s^{\text{GR}}[k^{\text{obs}}, \gamma_{\text{timing}}^{\text{obs}}]}\right]_{1534+12} = 1.000 \pm 0.007.$$
 (20.19)

The discovery of the binary pulsar PSR J1141 - 6545 [46](whose companion is probably a white dwarf) has allowed one to measure four observable parameters: $k, \gamma_{\text{timing}}, \dot{P}_b$ [47,48], and the parameter s [49,48]. The latter parameter (which is equal to the sine of the inclination angle, $s = \sin i$) was consistently measured in two ways: from a scintillation analysis [49], and from timing measurements [48]. General Relativity passes all the corresponding tests within measurement accuracy. See Fig. 20.1 which uses the (more precise) scintillation measurement of $s = \sin i$.

The discovery of the remarkable double binary pulsar PSR J0737 — 3039 A and B [50,51] has led to the measurement of seven independent parameters [52,53]: five of them are the post-Keplerian parameters $k, \gamma_{\text{timing}}, r, s$ and \dot{P}_b entering the relativistic timing formula of the fast-spinning pulsar PSR J0737 - 3039 A, a sixth is the ratio $R = x_B/x_A$ between the projected semi-major axis of the more slowly spinning companion pulsar PSR J0737 - 3039 B, and that of PSR J0737 - 3039 A. [The theoretical prediction for the ratio $R = x_B/x_A$, considered as a function of the (inertial) masses $m_1 = m_A$ and $m_2 = m_B$, is $R^{\text{theory}} = m_1/m_2 + O((v/c)^4)$ [36], independently of the gravitational theory considered.] Finally, the seventh parameter $\Omega_{\rm SO,B}$ is the angular rate of (spin-orbit) precession of PSR J0737 - 3039 B around the total angular momentum [53]. These seven measurements give us five tests of relativistic gravity [52,54]. General Relativity passes all those tests with flying colors (see Fig. 20.1). Let us highlight here two of them.

One test is a new, precise confirmation of the reality of gravitational radiation

$$\left[\frac{\dot{P}_b^{\text{obs}}}{\dot{P}_b^{\text{GR}}[k^{\text{obs}}, R^{\text{obs}}]}\right]_{0737-3039} = 1.003 \pm 0.014 \ .$$
(20.20)

Another one is an accurate (5 \times 10⁻⁴ level) new strong-field confirmation of General Relativity:

$$\left[\frac{s^{\rm obs}}{s^{\rm GR}[k^{\rm obs},R^{\rm obs}]}\right]_{0737-3039} = 0.99987 \pm 0.00050 \ . \eqno(20.21)$$

Fig. 20.1 illustrates all the tests of strong-field and radiative gravity derived from the above-mentioned binary pulsars: (3-2=) one test from PSR1913 + 16, (5-2=) 3 tests from PSR1534 + 12, (4-2=) 2 tests from PSR J1141 - 6545, and (7-2=) 5 tests from PSR J0737 - 3039

Data from several nearly circular binary systems (made of a neutron star and a white dwarf) have also led to strong-field confirmations (at the 4.6×10^{-3} level) of the 'strong equivalence principle,' *i.e.*, the fact that neutron stars and white dwarfs fall with the same acceleration in the gravitational field of the Galaxy [55,56]. The measurements of \dot{P}_b in some pulsar-white dwarf systems lead to strong constraints on the variation of Newton's G_N , and on the existence of gravitational dipole radiation [57,58]. In addition, arrays of millisecond pulsars are sensitive detectors of (very low frequency) gravitational waves [59].

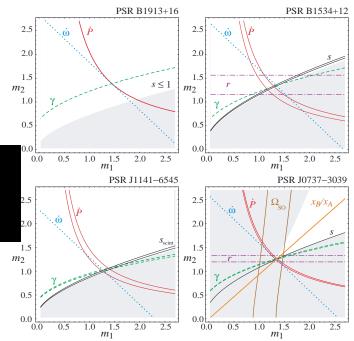

Figure 20.1: Illustration of the *eleven* tests of relativistic gravity obtained in the four different binary pulsar systems: PSR1913 + 16 (one test), PSR1534 + 12 (3 tests), PSR J1141 – 6545 (2 tests), and PSR J0737 – 3039 A,B (5 tests). Each curve (or strip) in the mass plane corresponds to the interpretation, within General Relativity, of some observable parameter among: \dot{P}_b , $k \equiv \dot{\omega} P_b/2\pi$, $\gamma_{\rm timing}$, r, $s = \sin i$, $\Omega_{\rm SO,B}$ and R. (Figure updated from [61]; courtesy of G. Esposito-Farèse.)

They constrain the contribution $\Omega_{gw}(f)$ to the critical cosmological density of a stochastic background of gravitational waves to the level $\Omega_{gw}(1/(8\mathrm{yr})) < 2 \times 10^{-8} h^{-2}$ [60](here, h denotes the normalized Hubble expansion rate).

The constraints on tensor-scalar theories provided by the various binary-pulsar "experiments" have been analyzed in [38,61,62] and shown to exclude a large portion of the parameter space allowed by solar-system tests. Finally, measurements over several years of the pulse profiles of various pulsars have detected secular profile changes compatible with the prediction [63] that the general relativistic spin-orbit coupling should cause a secular change in the orientation of the pulsar beam with respect to the line of sight ("geodetic precession"). Such confirmations of general-relativistic spin-orbit effects were obtained in PSR 1913+16 [64], PSR B1534+12 [65], PSR J1141-6545 [66], and PSR J0737 - 3039 [53].

The tests considered above have examined the gravitational interaction on scales between a fraction of a millimeter and a few astronomical units. On the other hand, the general relativistic action on light and matter of an external gravitational field have been verified on much larger scales in many gravitational lensing systems. For quantitative tests on kiloparsec scales see Ref. 67. Some tests on cosmological scales are also available [68].

20.4. Conclusions

All present experimental tests are compatible with the predictions of the current "standard" theory of gravitation: Einstein's General Relativity. The universality of the coupling between matter and gravity (Equivalence Principle) has been verified around the 10^{-13} level. Solar system experiments have tested the weak-field predictions of Einstein's theory at the 10^{-4} level (and down to the 2×10^{-5} level for the post-Einstein parameter $\overline{\gamma}$). The propagation properties of relativistic gravity, as well as several of its strong-field aspects, have been verified at the 10^{-3} level in binary pulsar experiments. Recent laboratory experiments have also set strong constraints on sub-millimeter modifications of Newtonian gravity.

21. BIG-BANG COSMOLOGY

Revised September 2011 by K.A. Olive (University of Minnesota) and J.A. Peacock (University of Edinburgh).

21.1. Introduction to Standard Big-Bang Model

The observed expansion of the Universe [1,2,3] is a natural (almost inevitable) result of any homogeneous and isotropic cosmological model based on general relativity. However, by itself, the Hubble expansion does not provide sufficient evidence for what we generally refer to as the Big-Bang model of cosmology. While general relativity is in principle capable of describing the cosmology of any given distribution of matter, it is extremely fortunate that our Universe appears to be homogeneous and isotropic on large scales. Together, homogeneity and isotropy allow us to extend the Copernican Principle to the Cosmological Principle, stating that all spatial positions in the Universe are essentially equivalent.

The formulation of the Big-Bang model began in the 1940s with the work of George Gamow and his collaborators. Alpher and Herman. In order to account for the possibility that the abundances of the elements had a cosmological origin, they proposed that the early Universe which was once very hot and dense (enough so as to allow for the nucleosynthetic processing of hydrogen), and has expanded and cooled to its present state [4,5]. In 1948, Alpher and Herman predicted that a direct consequence of this model is the presence of a relic background radiation with a temperature of order a few K [6,7]. Of course this radiation was observed 16 years later as the microwave background radiation [8]. Indeed, it was the observation of the 3 K background radiation that singled out the Big-Bang model as the prime candidate to describe our Universe. Subsequent work on Big-Bang nucleosynthesis further confirmed the necessity of our hot and dense past. (See the review on BBN—Sec. 22 of this Review for a detailed discussion of BBN.) These relativistic cosmological models face severe problems with their initial conditions, to which the best modern solution is inflationary cosmology, discussed in Sec. 21.3.5. If correct, these ideas would strictly render the term 'Big Bang' redundant, since it was first coined by Hoyle to represent a criticism of the lack of understanding of the initial conditions.

21.1.1. The Robertson-Walker Universe:

The observed homogeneity and isotropy enable us to describe the overall geometry and evolution of the Universe in terms of two cosmological parameters accounting for the spatial curvature and the overall expansion (or contraction) of the Universe. These two quantities appear in the most general expression for a space-time metric which has a (3D) maximally symmetric subspace of a 4D space-time, known as the Robertson-Walker metric:

$$ds^{2} = dt^{2} - R^{2}(t) \left[\frac{dr^{2}}{1 - kr^{2}} + r^{2} \left(d\theta^{2} + \sin^{2}\theta \, d\phi^{2} \right) \right] . \tag{21.1}$$

Note that we adopt c=1 throughout. By rescaling the radial coordinate, we can choose the curvature constant k to take only the discrete values +1, -1, or 0 corresponding to closed, open, or spatially flat geometries. In this case, it is often more convenient to re-express the metric as

$$ds^{2} = dt^{2} - R^{2}(t) \left[d\chi^{2} + S_{k}^{2}(\chi) \left(d\theta^{2} + \sin^{2}\theta \, d\phi^{2} \right) \right] , \qquad (21.2)$$

where the function $S_k(\chi)$ is $(\sin\chi,\chi,\sinh\chi)$ for k=(+1,0,-1). The coordinate r (in Eq. (21.1)) and the 'angle' χ (in Eq. (21.2)) are both dimensionless; the dimensions are carried by R(t), which is the cosmological scale factor which determines proper distances in terms of the comoving coordinates. A common alternative is to define a dimensionless scale factor, $a(t)=R(t)/R_0$, where $R_0\equiv R(t_0)$ is R at the present epoch. It is also sometimes convenient to define a dimensionless or conformal time coordinate, η , by $d\eta=dt/R(t)$. Along constant spatial sections, the proper time is defined by the time coordinate, t. Similarly, for $dt=d\theta=d\phi=0$, the proper distance is given by $R(t)\chi$. For standard texts on cosmological models see e.g., Refs. [9–16].

21.1.2. The redshift:

The cosmological redshift is a direct consequence of the Hubble expansion, determined by R(t). A local observer detecting light from a distant emitter sees a redshift in frequency. We can define the redshift as

$$z \equiv \frac{\nu_1 - \nu_2}{\nu_2} \simeq \frac{\nu_{12}}{c} \ , \tag{21.3}$$

where ν_1 is the frequency of the emitted light, ν_2 is the observed frequency and v_{12} is the relative velocity between the emitter and the observer. While the definition, $z=(\nu_1-\nu_2)/\nu_2$ is valid on all distance scales, relating the redshift to the relative velocity in this simple way is only true on small scales (*i.e.*, less than cosmological scales) such that the expansion velocity is non-relativistic. For light signals, we can use the metric given by Eq. (21.1) and $ds^2=0$ to write

$$\frac{v_{12}}{c} = \dot{R} \, \delta r = \frac{\dot{R}}{R} \, \delta t = \frac{\delta R}{R} = \frac{R_2 - R_1}{R_1} \,,$$
 (21.4)

where $\delta r(\delta t)$ is the radial coordinate (temporal) separation between the emitter and observer. Thus, we obtain the simple relation between the redshift and the scale factor

$$1 + z = \frac{\nu_1}{\nu_2} = \frac{R_2}{R_1} \ . \tag{21.5}$$

This result does not depend on the non-relativistic approximation.

21.1.3. The Friedmann-Lemaître equations of motion:

The cosmological equations of motion are derived from Einstein's equations ${\bf r}$

$$\mathcal{R}_{\mu\nu} - \frac{1}{2}g_{\mu\nu}\mathcal{R} = 8\pi G_{\rm N}T_{\mu\nu} + \Lambda g_{\mu\nu} . \qquad (21.6)$$

Gliner [17] and Zeldovich [18] have pioneered the modern view, in which the Λ term is taken to the rhs and interpreted as an effective energy–momentum tensor $T_{\mu\nu}$ for the vacuum of $\Lambda g_{\mu\nu}/8\pi G_{\rm N}$. It is common to assume that the matter content of the Universe is a perfect fluid, for which

$$T_{\mu\nu} = -pg_{\mu\nu} + (p+\rho)u_{\mu}u_{\nu} , \qquad (21.7)$$

where $g_{\mu\nu}$ is the space-time metric described by Eq. (21.1), p is the isotropic pressure, ρ is the energy density and u=(1,0,0,0) is the velocity vector for the isotropic fluid in co-moving coordinates. With the perfect fluid source, Einstein's equations lead to the Friedmann-Lemaître equations

$$H^2 \equiv \left(\frac{\dot{R}}{R}\right)^2 = \frac{8\pi G_N \rho}{3} - \frac{k}{R^2} + \frac{\Lambda}{3}$$
, (21.8)

and

$$\frac{\ddot{R}}{R} = \frac{\Lambda}{3} - \frac{4\pi G_{\rm N}}{3} \ (\rho + 3p) \ , \tag{21.9}$$

where H(t) is the Hubble parameter and Λ is the cosmological constant. The first of these is sometimes called the Friedmann equation. Energy conservation via $T^{\mu\nu}_{;\mu}=0$, leads to a third useful equation [which can also be derived from Eq. (21.8) and Eq. (21.9)]

$$\dot{\rho} = -3H\left(\rho + p\right) \ . \tag{21.10}$$

Eq. (21.10) can also be simply derived as a consequence of the first law of thermodynamics.

Eq. (21.8) has a simple classical mechanical analog if we neglect (for the moment) the cosmological term Λ . By interpreting $-k/R^2$ Newtonianly as a 'total energy', then we see that the evolution of the Universe is governed by a competition between the potential energy, $8\pi G_{\rm N} \rho/3$, and the kinetic term $(\dot{R}/R)^2$. For $\Lambda=0$, it is clear that the Universe must be expanding or contracting (except at the turning point prior to collapse in a closed Universe). The ultimate fate of the Universe is determined by the curvature constant k. For k=+1, the Universe will recollapse in a finite time, whereas for k=0,-1, the Universe will expand indefinitely. These simple conclusions can be altered when $\Lambda \neq 0$ or more generally with some component with $(\rho+3p)<0$.

${\bf 21.1.4.} \quad Definition \ of \ cosmological \ parameters:$

In addition to the Hubble parameter, it is useful to define several other measurable cosmological parameters. The Friedmann equation can be used to define a critical density such that k=0 when $\Lambda=0$,

$$\rho_c \equiv \frac{3H^2}{8\pi G_{\rm N}} = 1.88 \times 10^{-26} \, h^2 \, \text{kg m}^{-3}$$
$$= 1.05 \times 10^{-5} \, h^2 \, \text{GeV cm}^{-3} , \qquad (21.11)$$

where the scaled Hubble parameter, h, is defined by

$$H \equiv 100 h \text{ km s}^{-1} \text{ Mpc}^{-1}$$

 $\Rightarrow H^{-1} = 9.78 h^{-1} \text{ Gyr}$ (21.12)
 $= 2998 h^{-1} \text{ Mpc}$.

The cosmological density parameter Ω_{tot} is defined as the energy density relative to the critical density,

$$\Omega_{\text{tot}} = \rho/\rho_c \ . \tag{21.13}$$

Note that one can now rewrite the Friedmann equation as

$$k/R^2 = H^2(\Omega_{\text{tot}} - 1)$$
 (21.14)

From Eq. (21.14), one can see that when $\Omega_{\rm tot} > 1$, k = +1 and the Universe is closed, when $\Omega_{\rm tot} < 1$, k = -1 and the Universe is open, and when $\Omega_{\rm tot} = 1$, k = 0, and the Universe is spatially flat.

It is often necessary to distinguish different contributions to the density. It is therefore convenient to define present-day density parameters for pressureless matter $(\Omega_{\rm m})$ and relativistic particles $(\Omega_{\rm r})$, plus the quantity $\Omega_{\Lambda} = \Lambda/3H^2$. In more general models, we may wish to drop the assumption that the vacuum energy density is constant, and we therefore denote the present-day density parameter of the vacuum by $\Omega_{\rm v}$. The Friedmann equation then becomes

$$k/R_0^2 = H_0^2(\Omega_{\rm m} + \Omega_{\rm r} + \Omega_{\rm v} - 1)$$
, (21.15)

where the subscript 0 indicates present-day values. Thus, it is the sum of the densities in matter, relativistic particles, and vacuum that determines the overall sign of the curvature. Note that the quantity $-k/R_0^2H_0^2$ is sometimes referred to as Ω_k . This usage is unfortunate: it encourages one to think of curvature as a contribution to the energy density of the Universe, which is not correct.

21.1.5. Standard Model solutions:

Much of the history of the Universe in the standard Big-Bang model can be easily described by assuming that either matter or radiation dominates the total energy density. During inflation and again today the expansion rate for the Universe is accelerating, and domination by a cosmological constant or some other form of dark energy should be considered. In the following, we shall delineate the solutions to the Friedmann equation when a single component dominates the energy density. Each component is distinguished by an equation of state parameter $w=p/\rho$.

21.1.5.1. Solutions for a general equation of state:

Let us first assume a general equation of state parameter for a single component, w which is constant. In this case, Eq. (21.10) can be written as $\dot{\rho} = -3(1+w)\rho\dot{R}/R$ and is easily integrated to yield

$$\rho \propto R^{-3(1+w)}$$
 (21.16)

Note that at early times when R is small, the less singular curvature term k/R^2 in the Friedmann equation can be neglected so long as w>-1/3. Curvature domination occurs at rather late times (if a cosmological constant term does not dominate sooner). For $w\neq -1$, one can insert this result into the Friedmann equation Eq. (21.8), and if one neglects the curvature and cosmological constant terms, it is easy to integrate the equation to obtain,

$$R(t) \propto t^{2/[3(1+w)]}$$
 . (21.17)

21.1.5.2. A Radiation-dominated Universe:

In the early hot and dense Universe, it is appropriate to assume an equation of state corresponding to a gas of radiation (or relativistic particles) for which w=1/3. In this case, Eq. (21.16) becomes $\rho \propto R^{-4}$. The 'extra' factor of 1/R is due to the cosmological redshift; not only is the number density of particles in the radiation background decreasing as R^{-3} since volume scales as R^3 , but in addition, each particle's energy is decreasing as $E \propto \nu \propto R^{-1}$. Similarly, one can substitute w=1/3 into Eq. (21.17) to obtain

$$R(t) \propto t^{1/2}$$
; $H = 1/2t$. (21.18)

21.1.5.3. A Matter-dominated Universe:

At relatively late times, non-relativistic matter eventually dominates the energy density over radiation (see Sec. 21.3.8). A pressureless gas (w=0) leads to the expected dependence $\rho \propto R^{-3}$ from Eq. (21.16) and, if k=0, we get

$$R(t) \propto t^{2/3}$$
; $H = 2/3t$. (21.19)

21.1.5.4. A Universe dominated by vacuum energy:

If there is a dominant source of vacuum energy, V_0 , it would act as a cosmological constant with $\Lambda = 8\pi G_{\rm N} V_0$ and equation of state w=-1. In this case, the solution to the Friedmann equation is particularly simple and leads to an exponential expansion of the Universe

$$R(t) \propto e^{\sqrt{\Lambda/3}t}$$
 (21.20)

A key parameter is the equation of state of the vacuum, $w \equiv p/\rho$: this need not be the w=-1 of Λ , and may not even be constant [19,20,21]. There is now much interest in the more general possibility of a dynamically evolving vacuum energy, for which the name 'dark energy' has become commonly used. A variety of techniques exist whereby the vacuum density as a function of time may be measured, usually expressed as the value of w as a function of epoch [22,23]. The best current measurement for the equation of state (assumed constant, but without assuming zero curvature) is $w=-1.00\pm0.06$ [24]. Unless stated otherwise, we will assume that the vacuum energy is a cosmological constant with w=-1 exactly.

The presence of vacuum energy can dramatically alter the fate of the Universe. For example, if $\Lambda < 0$, the Universe will eventually recollapse independent of the sign of k. For large values of $\Lambda > 0$ (larger than the Einstein static value needed to halt any cosmological expansion or contraction), even a closed Universe will expand forever. One way to quantify this is the deceleration parameter, q_0 , defined as

$$q_0 = -\frac{R\ddot{R}}{\dot{R}^2}\Big|_{0} = \frac{1}{2}\Omega_{\rm m} + \Omega_{\rm r} + \frac{(1+3w)}{2}\Omega_{\rm v}$$
 (21.21)

This equation shows us that w<-1/3 for the vacuum may lead to an accelerating expansion. To the continuing astonishment of cosmologists, such an effect has been observed; one piece of direct evidence is the Supernova Hubble diagram [26–32] (see Fig. 21.1 below); current data indicate that vacuum energy is indeed the largest contributor to the cosmological density budget, with $\Omega_{\rm v}=0.73\pm0.03$ and $\Omega_{\rm m}=0.27\pm0.03$ if k=0 is assumed (7-year mean WMAP) [24].

The existence of this constituent is without doubt the greatest puzzle raised by the current cosmological model; the final section of this review discusses some of the ways in which the vacuum-energy problem is being addressed.

21.2. Introduction to Observational Cosmology

21.2.1. Fluxes, luminosities, and distances:

The key quantities for observational cosmology can be deduced quite directly from the metric.

(1) The proper transverse size of an object seen by us to subtend an angle $d\psi$ is its comoving size $d\psi \, S_k(\chi)$ times the scale factor at the time of emission:

$$d\ell = d\psi \ R_0 S_k(\chi)/(1+z)$$
 . (21.22)

(2) The apparent flux density of an object is deduced by allowing its photons to flow through a sphere of current radius $R_0S_k(\chi)$; but photon energies and arrival rates are redshifted, and the bandwidth $d\nu$ is reduced. The observed photons at frequency ν_0 were emitted at frequency $\nu_0(1+z)$, so the flux density is the luminosity at this frequency, divided by the total area, divided by 1+z:

$$S_{\nu}(\nu_0) = \frac{L_{\nu}([1+z]\nu_0)}{4\pi R_0^2 S_{\nu}^2(\chi)(1+z)}.$$
 (21.23)

These relations lead to the following common definitions:

angular-diameter distance:
$$D_{\rm A} = (1+z)^{-1} R_0 S_k(\chi)$$

luminosity distance: $D_{\rm L} = (1+z) R_0 S_k(\chi)$. (21.24)

These distance-redshift relations are expressed in terms of observables by using the equation of a null radial geodesic $(R(t)d\chi = dt)$ plus the Friedmann equation:

$$R_0 d\chi = \frac{1}{H(z)} dz = \frac{1}{H_0} \left[(1 - \Omega_{\rm m} - \Omega_{\rm v} - \Omega_{\rm r}) (1 + z)^2 + \Omega_{\rm v} (1 + z)^{3+3w} + \Omega_{\rm m} (1 + z)^3 + \Omega_{\rm r} (1 + z)^4 \right]^{-1/2} dz .$$
(21.25)

The main scale for the distance here is the Hubble length, $1/H_0$.

The flux density is the product of the specific intensity I_{ν} and the solid angle $d\Omega$ subtended by the source: $S_{\nu} = I_{\nu} \ d\Omega$. Combining the angular size and flux-density relations thus gives the relativistic version of surface-brightness conservation:

$$I_{\nu}(\nu_0) = \frac{B_{\nu}([1+z]\nu_0)}{(1+z)^3} , \qquad (21.26)$$

where B_{ν} is surface brightness (luminosity emitted into unit solid angle per unit area of source). We can integrate over ν_0 to obtain the corresponding total or bolometric formula:

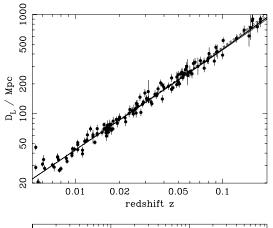

$$I_{\text{tot}} = \frac{B_{\text{tot}}}{(1+z)^4} \ .$$
 (21.27)

This cosmology-independent form expresses Liouville's Theorem: photon phase-space density is conserved along rays.

21.2.2. Distance data and geometrical tests of cosmology:

In order to confront these theoretical predictions with data, we have to bridge the divide between two extremes. Nearby objects may have their distances measured quite easily, but their radial velocities are dominated by deviations from the ideal Hubble flow, which typically have a magnitude of several hundred ${\rm km\,s^{-1}}.$ On the other hand, objects at redshifts $z\gtrsim 0.01$ will have observed recessional velocities that differ from their ideal values by $\lesssim 10\%,$ but absolute distances are much harder to supply in this case. The traditional solution to this problem is the construction of the distance ladder: an interlocking set of methods for obtaining relative distances between various classes of object, which begins with absolute distances at the 10 to 100 pc level, and terminates with galaxies at significant redshifts. This is reviewed in the review on Cosmological Parameters—Sec. 23 of this Review.

By far the most exciting development in this area has been the use of type Ia Supernovae (SNe), which now allow measurement of relative distances with 5% precision. In combination with Cepheid data from the HST and a direct geometrical distance to the maser

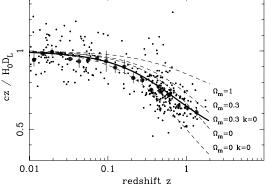

Figure 21.1: The type Ia supernova Hubble diagram [26–30]. The first panel shows that for $z \ll 1$ the large-scale Hubble flow is indeed linear and uniform; the second panel shows an expanded scale, with the linear trend divided out, and with the redshift range extended to show how the Hubble law becomes nonlinear. ($\Omega_{\rm r}=0$ is assumed.) Larger points with errors show median values in redshift bins. Comparison with the prediction of Friedmann-Lemaître models appears to favor a vacuum-dominated Universe.

galaxy NGC4258, SNe results extend the distance ladder to the point where deviations from uniform expansion are negligible, leading to the best existing direct value for H_0 : $73.8 \pm 2.4 \, \mathrm{km \, s^{-1} Mpc^{-1}}$ [25]. Better still, the analysis of high-z SNe has allowed the first meaningful test of cosmological geometry to be carried out: as shown in Fig. 21.1 and Fig. 21.2, a combination of supernova data and measurements of microwave-background anisotropies strongly favors a k=0 model dominated by vacuum energy. (See the review on Cosmological Parameters—Sec. 23 of this Review for a more comprehensive review of Hubble parameter determinations.)

21.2.3. Age of the Universe:

The most striking conclusion of relativistic cosmology is that the Universe has not existed forever. The dynamical result for the age of the Universe may be written as

$$H_0 t_0 = \int_0^\infty \frac{dz}{(1+z)H(z)}$$

$$= \int_0^\infty \frac{dz}{(1+z)\left[(1+z)^2(1+\Omega_{\rm m}z) - z(2+z)\Omega_{\rm v}\right]^{1/2}} , \quad (21.28)$$

where we have neglected $\Omega_{\rm r}$ and chosen w=-1. Over the range of interest $(0.1 \lesssim \Omega_{\rm m} \lesssim 1, \ |\Omega_{\rm v}| \lesssim 1)$, this exact answer may be approximated to a few % accuracy by

$$H_0 t_0 \simeq \frac{2}{3} (0.7\Omega_{\rm m} + 0.3 - 0.3\Omega_{\rm v})^{-0.3}$$
 (21.29)

For the special case that $\Omega_{\rm m}+\Omega_{\rm v}=1,$ the integral in Eq. (21.28) can be expressed analytically as

$$H_0 t_0 = \frac{2}{3\sqrt{\Omega_{\rm v}}} \ln \frac{1 + \sqrt{\Omega_{\rm v}}}{\sqrt{1 - \Omega_{\rm v}}} \quad (\Omega_{\rm m} < 1) .$$
 (21.30)

The most accurate means of obtaining ages for astronomical objects is based on the natural clocks provided by radioactive decay. The use of these clocks is complicated by a lack of knowledge of the initial conditions of the decay. In the Solar System, chemical fractionation of different elements helps pin down a precise age for the pre-Solar nebula of 4.6 Gyr, but for stars it is necessary to attempt an a priori calculation of the relative abundances of nuclei that result from supernova explosions. In this way, a lower limit for the age of stars in the local part of the Milky Way of about 11 Gyr is obtained [36,37].

The other major means of obtaining cosmological age estimates is based on the theory of stellar evolution. In principle, the main-sequence turnoff point in the color-magnitude diagram of a globular cluster should yield a reliable age. However, these have been controversial owing to theoretical uncertainties in the evolution model, as well as observational uncertainties in the distance, dust extinction, and metallicity of clusters. The present consensus favors ages for the oldest clusters of about 12 Gyr [38,39].

These methods are all consistent with the age deduced from studies of structure formation, using the microwave background and large-scale structure: $t_0=13.77\pm0.13$ Gyr [24], where the extra accuracy comes at the price of assuming the Cold Dark Matter model to be true.

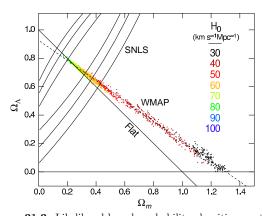

Figure 21.2: Likelihood-based probability densities on the plane Ω_{Λ} (i.e., $\Omega_{\rm v}$ assuming w=-1) vs $\Omega_{\rm m}$. The colored Monte-Carlo points derive from WMAP [34] and show that the CMB alone requires a flat universe $\Omega_{\rm v}+\Omega_{\rm m}\simeq 1$ if the Hubble constant is not too high. The SNe Ia results [35] very nearly constrain the orthogonal combination $\Omega_{\rm v}-\Omega_{\rm m}$. The intersection of these constraints is the most direct (but far from the only) piece of evidence favoring a flat model with $\Omega_{\rm m}\simeq 0.25$.

21.2.4. Horizon, isotropy, flatness problems:

For photons, the radial equation of motion is just $c dt = R d\chi$. How far can a photon get in a given time? The answer is clearly

$$\Delta \chi = \int_{t_1}^{t_2} \frac{dt}{R(t)} \equiv \Delta \eta , \qquad (21.31)$$

i.e., just the interval of conformal time. We can replace dt by dR/\dot{R} , which the Friedmann equation says is $\propto dR/\sqrt{\rho R^2}$ at early times. Thus, this integral converges if $\rho R^2 \to \infty$ as $t_1 \to 0$, otherwise it diverges. Provided the equation of state is such that ρ changes faster than R^{-2} , light signals can only propagate a finite distance between the Big Bang and the present; there is then said to be a particle horizon. Such a horizon therefore exists in conventional Big-Bang models, which are dominated by radiation $(\rho \propto R^{-4})$ at early times.

At late times, the integral for the horizon is largely determined by the matter-dominated phase, for which

$$D_{\rm H} = R_0 \, \chi_{\rm H} \equiv R_0 \, \int_0^{t(z)} \frac{dt}{R(t)} \simeq \frac{6000}{\sqrt{\Omega z}} \, h^{-1} \,{\rm Mpc} \quad (z \gg 1) \,. \quad (21.32)$$

The horizon at the time of formation of the microwave background ('last scattering:' $z \simeq 1100$) was thus of order 100 Mpc in size, subtending an angle of about 1°. Why then are the large number of causally disconnected regions we see on the microwave sky all at the same temperature? The Universe is very nearly isotropic and homogeneous, even though the initial conditions appear not to permit such a state to be constructed.

A related problem is that the $\Omega = 1$ Universe is unstable:

$$\Omega(a) - 1 = \frac{\Omega - 1}{1 - \Omega + \Omega_{\rm v} a^2 + \Omega_{\rm m} a^{-1} + \Omega_{\rm r} a^{-2}} , \qquad (21.33)$$

where Ω with no subscript is the total density parameter, and $a(t) = R(t)/R_0$. This requires $\Omega(t)$ to be unity to arbitrary precision as the initial time tends to zero; a universe of non-zero curvature today requires very finely tuned initial conditions.

21.3. The Hot Thermal Universe

21.3.1. Thermodynamics of the early Universe:

As alluded to above, we expect that much of the early Universe can be described by a radiation-dominated equation of state. In addition, through much of the radiation-dominated period, thermal equilibrium is established by the rapid rate of particle interactions relative to the expansion rate of the Universe (see Sec. 21.3.3 below). In equilibrium, it is straightforward to compute the thermodynamic quantities, ρ, p , and the entropy density, s. In general, the energy density for a given particle type i can be written as

$$\rho_i = \int E_i \, dn_{q_i} \,, \tag{21.34}$$

with the density of states given by

$$dn_{q_i} = \frac{g_i}{2\pi^2} \left(\exp[(E_{q_i} - \mu_i)/T_i] \pm 1 \right)^{-1} q_i^2 dq_i ,$$
 (21.35)

where g_i counts the number of degrees of freedom for particle type i, $E_{q_i}^2 = m_i^2 + q_i^2$, μ_i is the chemical potential, and the \pm corresponds to either Fermi or Bose statistics. Similarly, we can define the pressure of a perfect gas as

$$p_i = \frac{1}{3} \int \frac{q_i^2}{E_i} \, dn_{q_i} \ . \tag{21.36}$$

The number density of species i is simply

$$n_i = \int dn_{q_i} , \qquad (21.37)$$

and the entropy density is

$$s_i = \frac{\rho_i + p_i - \mu_i n_i}{T} \ . \tag{21.38}$$

In the Standard Model, a chemical potential is often associated with baryon number, and since the net baryon density relative to the photon density is known to be very small (of order 10^{-10}), we can neglect any such chemical potential when computing total thermodynamic quantities.

For photons, we can compute all of the thermodynamic quantities rather easily. Taking $g_i=2$ for the 2 photon polarization states, we have (in units where $\hbar=k_B=1$)

$$\rho_{\gamma} = \frac{\pi^2}{15} T^4 \; ; \quad \ p_{\gamma} = \frac{1}{3} \rho_{\gamma} \; ; \quad \ s_{\gamma} = \frac{4 \rho_{\gamma}}{3T} \; ; \quad \ n_{\gamma} = \frac{2 \zeta(3)}{\pi^2} T^3 \; , \quad (21.39)$$

with $2\zeta(3)/\pi^2 \simeq 0.2436$. Note that Eq. (21.10) can be converted into an equation for entropy conservation. Recognizing that $\dot{p} = s\dot{T}$, Eq. (21.10) becomes

$$d(sR^3)/dt = 0. (21.40)$$

For radiation, this corresponds to the relationship between expansion and cooling, $T \propto R^{-1}$ in an adiabatically expanding universe. Note also that both s and n_{γ} scale as T^3 .

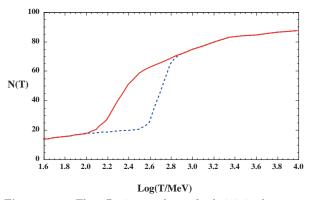

Figure 21.3: The effective numbers of relativistic degrees of freedom as a function of temperature. The sharp drop corresponds to the quark-hadron transition. The solid curve assume a QCD scale of $150~{\rm MeV}$, while the dashed curve assumes $450~{\rm MeV}$.

21.3.2. Radiation content of the Early Universe:

At the very high temperatures associated with the early Universe, massive particles are pair produced, and are part of the thermal bath. If for a given particle species i we have $T\gg m_i$, then we can neglect the mass in Eq. (21.34) to Eq. (21.38), and the thermodynamic quantities are easily computed as in Eq. (21.39). In general, we can approximate the energy density (at high temperatures) by including only those particles with $m_i\ll T$. In this case, we have

$$\rho = \left(\sum_{B} g_{B} + \frac{7}{8} \sum_{F} g_{F}\right) \frac{\pi^{2}}{30} T^{4} \equiv \frac{\pi^{2}}{30} N(T) T^{4} , \qquad (21.41)$$

where $g_{B(F)}$ is the number of degrees of freedom of each boson (fermion) and the sum runs over all boson and fermion states with $m \ll T$. The factor of 7/8 is due to the difference between the Fermi and Bose integrals. Eq. (21.41) defines the effective number of degrees of freedom, N(T), by taking into account new particle degrees of freedom as the temperature is raised. This quantity is plotted in Fig. 21.3 [40].

The value of N(T) at any given temperature depends on the particle physics model. In the standard $\mathrm{SU}(3) \times \mathrm{SU}(2) \times \mathrm{U}(1)$ model, we can specify N(T) up to temperatures of $\mathrm{O}(100)$ GeV. The change in N (ignoring mass effects) can be seen in the table below.

| Temperature | New Particles | 4N(T) |
|---------------------------------|----------------------------------------------|-------|
| $T < m_e$ | γ 's + ν 's | 29 |
| $m_e < T < m_\mu$ | e^{\pm} | 43 |
| $m_{\mu} < T < m_{\pi}$ | μ^{\pm} | 57 |
| $m_{\pi} < T < {T_c}^{\dagger}$ | π 's | 69 |
| $T_c < T < m_{\text{strange}}$ | π 's + u, \bar{u}, d, \bar{d} + gluons | 205 |
| $m_s < T < m_{\rm charm}$ | $s,ar{s}$ | 247 |
| $m_c < T < m_{\tau}$ | $c, ar{c}$ | 289 |
| $m_{\tau} < T < m_{ m bottom}$ | $	au^\pm$ | 303 |
| $m_b < T < m_{W,Z}$ | $b, ar{b}$ | 345 |
| $m_{W,Z} < T < m_{ m Higgs}$ | W^{\pm}, Z | 381 |
| $m_H < T < m_{\rm top}$ | H^0 | 385 |
| $m_t < T$ | $t,ar{t}$ | 427 |

 $^{\dagger}T_{c}$ corresponds to the confinement-deconfinement transition between quarks and hadrons.

At higher temperatures, N(T) will be model-dependent. For example, in the minimal SU(5) model, one needs to add 24 states to N(T) for the X and Y gauge bosons, another 24 from the adjoint Higgs, and another 6 (in addition to the 4 already counted in W^{\pm} , Z, and H) from the $\overline{5}$ of Higgs. Hence for $T>m_X$ in minimal SU(5), N(T)=160.75. In a supersymmetric model this would at least double, with some changes possibly necessary in the table if the lightest supersymmetric particle has a mass below m_t .

In the radiation-dominated epoch, Eq. (21.10) can be integrated (neglecting the T-dependence of N) giving us a relationship between the age of the Universe and its temperature

$$t = \left(\frac{90}{32\pi^3 G_N N(T)}\right)^{1/2} T^{-2} . \tag{21.42}$$

Put into a more convenient form

$$tT_{\text{MeV}}^2 = 2.4[N(T)]^{-1/2}$$
, (21.43)

where t is measured in seconds and T_{MeV} in units of MeV.

21.3.3. Neutrinos and equilibrium: Due to the expansion of the Universe, certain rates may be too slow to either establish or maintain equilibrium. Quantitatively, for each particle i, as a minimal condition for equilibrium, we will require that some rate Γ_i involving that type be larger than the expansion rate of the Universe or

$$\Gamma_i > H \ . \tag{21.44}$$

Recalling that the age of the Universe is determined by H^{-1} , this condition is equivalent to requiring that on average, at least one interaction has occurred over the lifetime of the Universe.

A good example for a process which goes in and out of equilibrium is the weak interactions of neutrinos. On dimensional grounds, one can estimate the thermally averaged scattering cross section

$$\langle \sigma v \rangle \sim O(10^{-2})T^2/m_{\rm W}^4$$
 (21.45)

for $T \lesssim m_{\rm W}$. Recalling that the number density of leptons is $n \propto T^3$, we can compare the weak interaction rate, $\Gamma_{\rm wk} \sim n \langle \sigma v \rangle$, with the expansion rate,

$$H = \left(\frac{8\pi G_{\rm N}\rho}{3}\right)^{1/2} = \left(\frac{8\pi^3}{90}N(T)\right)^{1/2}T^2/M_{\rm P}$$
$$\sim 1.66N(T)^{1/2}T^2/M_{\rm P},$$
 (21.46)

where the Planck mass $M_{\rm P} = G_{\rm N}^{-1/2} = 1.22 \times 10^{19} \; {\rm GeV}.$

Neutrinos will be in equilibrium when $\Gamma_{\rm wk} > H$ or

$$T > (500 \, m_W^4 / M_P)^{1/3} \sim 1 \text{ MeV}$$
 (21.47)

However, this condition assumes $T \ll m_{\rm W}$; for higher temperatures, we should write $\langle \sigma v \rangle \sim O(10^{-2})/T^2$, so that $\Gamma \sim 10^{-2}T$. Thus, in the very early stages of expansion, at temperatures $T \gtrsim 10^{-2} M_{\rm P}/\sqrt{N}$, equilibrium will not have been established.

Having attained a quasi-equilibrium stage, the Universe then cools further to the point where the interaction and expansion timescales match once again. The temperature at which these rates are equal is commonly referred to as the neutrino decoupling or freeze-out temperature and is defined by $\Gamma_{\rm wk}(T_d)=H(T_d)$. For $T< T_d$, neutrinos drop out of equilibrium. The Universe becomes transparent to neutrinos and their momenta simply redshift with the cosmic expansion. The effective neutrino temperature will simply fall with $T\sim 1/R$.

Soon after decoupling, e^{\pm} pairs in the thermal background begin to annihilate (when $T \lesssim m_e$). Because the neutrinos are decoupled, the energy released due to annihilation heats up the photon background relative to the neutrinos. The change in the photon temperature can be easily computed from entropy conservation. The neutrino entropy must be conserved separately from the entropy of interacting particles. A straightforward computation yields

$$T_{\nu} = (4/11)^{1/3} T_{\gamma} \simeq 1.9 \text{ K} .$$
 (21.48)

Today, the total entropy density is therefore given by

$$s = \frac{4}{3} \frac{\pi^2}{30} \left(2 + \frac{21}{4} (T_{\nu}/T_{\gamma})^3 \right) T_{\gamma}^3 = \frac{4}{3} \frac{\pi^2}{30} \left(2 + \frac{21}{11} \right) T_{\gamma}^3 = 7.04 \, n_{\gamma} . \tag{21.49}$$

Similarly, the total relativistic energy density today is given by

$$\rho_r = \frac{\pi^2}{30} \left[2 + \frac{21}{4} (T_\nu / T_\gamma)^4 \right] T_\gamma^4 \simeq 1.68 \rho_\gamma . \tag{21.50}$$

In practice, a small correction is needed to this, since neutrinos are not totally decoupled at e^{\pm} annihilation: the effective number of massless neutrino species is 3.04, rather than 3 [41].

This expression ignores neutrino rest masses, but current oscillation data require at least one neutrino eigenstate to have a mass exceeding 0.05 eV. In this minimal case, $\Omega_{\nu}h^2=5\times 10^{-4}$, so the neutrino contribution to the matter budget would be negligibly small (which is our normal assumption). However, a nearly degenerate pattern of mass eigenstates could allow larger densities, since oscillation experiments only measure differences in m^2 values. Note that a 0.05-eV neutrino has $kT_{\nu}=m_{\nu}$ at $z\simeq 297$, so the above expression for the total present relativistic density is really only an extrapolation. However, neutrinos are almost certainly relativistic at all epochs where the radiation content of the Universe is dynamically significant.

21.3.4. Field Theory and Phase transitions:

It is very likely that the Universe has undergone one or more phase transitions during the course of its evolution [42–45]. Our current vacuum state is described by $\mathrm{SU}(3)_c\times\,\mathrm{U}(1)_\mathrm{em},$ which in the Standard Model is a remnant of an unbroken $\mathrm{SU}(3)_c\times\,\mathrm{SU}(2)_L\times\,\mathrm{U}(1)_Y$ gauge symmetry. Symmetry breaking occurs when a non-singlet gauge field (the Higgs field in the Standard Model) picks up a non-vanishing vacuum expectation value, determined by a scalar potential. For example, a simple (non-gauged) potential describing symmetry breaking is $V(\phi)=\frac{1}{4}\lambda\phi^4-\frac{1}{2}\mu^2\phi^2+V(0).$ The resulting expectation value is simply $\langle\phi\rangle=\mu/\sqrt{\lambda}.$

In the early Universe, finite temperature radiative corrections typically add terms to the potential of the form $\phi^2 T^2$. Thus, at very high temperatures, the symmetry is restored and $\langle \phi \rangle = 0$. As the Universe cools, depending on the details of the potential, symmetry breaking will occur via a first order phase transition in which the field tunnels through a potential barrier, or via a second order transition in which the field evolves smoothly from one state to another (as would be the case for the above example potential).

The evolution of scalar fields can have a profound impact on the early Universe. The equation of motion for a scalar field ϕ can be derived from the energy-momentum tensor

$$T_{\mu\nu} = \partial_{\mu}\phi\partial_{\nu}\phi - \frac{1}{2}g_{\mu\nu}\partial_{\rho}\phi\partial^{\rho}\phi - g_{\mu\nu}V(\phi) . \qquad (21.51)$$

By associating $\rho = T_{00}$ and $p = R^{-2}(t)T_{ii}$ we have

$$\begin{split} \rho &= \frac{1}{2} \dot{\phi}^2 + \frac{1}{2} R^{-2}(t) (\nabla \phi)^2 + V(\phi) \\ p &= \frac{1}{2} \dot{\phi}^2 - \frac{1}{6} R^{-2}(t) (\nabla \phi)^2 - V(\phi) \ , \end{split} \tag{21.52}$$

and from Eq. (21.10) we can write the equation of motion (by considering a homogeneous region, we can ignore the gradient terms)

$$\ddot{\phi} + 3H\dot{\phi} = -\partial V/\partial\phi \ . \tag{21.53}$$

21.3.5. *Inflation* :

In Sec. 21.2.4, we discussed some of the problems associated with the standard Big-Bang model. However, during a phase transition, our assumptions of an adiabatically expanding universe are generally not valid. If, for example, a phase transition occurred in the early Universe such that the field evolved slowly from the symmetric state to the global minimum, the Universe may have been dominated by the vacuum energy density associated with the potential near $\phi \approx 0$. During this period of slow evolution, the energy density due to radiation will fall below the vacuum energy density, $\rho \ll V(0)$. When this happens, the expansion rate will be dominated by the constant V(0), and we obtain the exponentially expanding solution given in Eq. (21.20). When the field evolves towards the global minimum it will

begin to oscillate about the minimum, energy will be released during its decay, and a hot thermal universe will be restored. If released fast enough, it will produce radiation at a temperature $NT_R^{\ 4} \lesssim V(0)$. In this reheating process, entropy has been created and the final value of RT is greater than the initial value of RT. Thus, we see that, during a phase transition, the relation $RT \sim \text{constant}$ need not hold true. This is the basis of the inflationary Universe scenario [46–48].

If, during the phase transition, the value of RT changed by a factor of $O(10^{29})$, the cosmological problems discussed above would be solved. The observed isotropy would be generated by the immense expansion; one small causal region could get blown up, and thus our entire visible Universe would have been in thermal contact some time in the past. In addition, the density parameter Ω would have been driven to 1 (with exponential precision). Density perturbations will be stretched by the expansion, $\lambda \sim R(t)$. Thus it will appear that $\lambda \gg H^{-1}$ or that the perturbations have left the horizon, where in fact the size of the causally connected region is now no longer simply H^{-1} . However, not only does inflation offer an explanation for large scale perturbations, it also offers a source for the perturbations themselves through quantum fluctuations.

Early models of inflation were based on a first order phase transition of a Grand Unified Theory [49]. Although these models led to sufficient exponential expansion, completion of the transition through bubble percolation did not occur, and lack of bubble collisions meant that the interior of the bubbles was not reheated. Subsequent models of inflation [50,51] considered second-order transitions within Grand Unified theories, thus successfully ending inflation with reheating from oscillations of the scalar field. But these models predicted too high an amplitude of relic density fluctuations. As a result, current models of inflation postulate second-order transitions in a completely new scalar field: the inflaton, ϕ . The potential of this field, $V(\phi)$, needs to have a very low gradient and curvature in order to match observed metric fluctuations.

In viable inflation models of this type, reheated bubbles again typically do not percolate, so inflation is 'eternal' and continues with exponential expansion in the region outside bubbles. These causally disconnected bubble universes constitute a 'multiverse', where low-energy physics can vary between different bubbles. This has led to a controversial 'anthropic' approach to cosmology [82–84], where observer selection within the multiverse can be introduced as a means of understanding e.g. why the observed level of vacuum energy is so low (because larger values suppress growth of structure).

${\bf 21.3.6.} \quad Baryogenesis:$

The Universe appears to be populated exclusively with matter rather than antimatter. Indeed antimatter is only detected in accelerators or in cosmic rays. However, the presence of antimatter in the latter is understood to be the result of collisions of primary particles in the interstellar medium. There is in fact strong evidence against primary forms of antimatter in the Universe. Furthermore, the density of baryons compared to the density of photons is extremely small, $\eta \sim 10^{-10}$.

The production of a net baryon asymmetry requires baryon number violating interactions, C and CP violation and a departure from thermal equilibrium [52]. The first two of these ingredients are expected to be contained in grand unified theories as well as in the non-perturbative sector of the Standard Model, the third can be realized in an expanding universe where as we have seen interactions come in and out of equilibrium.

There are several interesting and viable mechanisms for the production of the baryon asymmetry. While, we can not review any of them here in any detail, we mention some of the important scenarios. In all cases, all three ingredients listed above are incorporated. One of the first mechanisms was based on the out of equilibrium decay of a massive particle such as a superheavy GUT gauge of Higgs boson [53,54]. A novel mechanism involving the decay of flat directions in supersymmetric models is known as the Affleck-Dine scenario [55]. There is also the possibility of generating the baryon asymmetry at the electro-weak scale using the non-perturbative interactions of sphalerons [56]. Because these interactions conserve the sum of baryon and lepton number, B+L, it is possible to first

generate a lepton asymmetry (e.g., by the out-of-equilibrium decay of a superheavy right-handed neutrino), which is converted to a baryon asymmetry at the electro-weak scale [57]. This mechanism is known as lepto-baryogenesis.

${\bf 21.3.7.} \quad Nucleosynthesis:$

An essential element of the standard cosmological model is Big-Bang nucleosynthesis (BBN), the theory which predicts the abundances of the light element isotopes D, 3 He, 4 He, and 7 Li. Nucleosynthesis takes place at a temperature scale of order 1 MeV. The nuclear processes lead primarily to 4 He, with a primordial mass fraction of about 25%. Lesser amounts of the other light elements are produced: about 10^{-5} of D and 3 He and about 10^{-10} of 7 Li by number relative to H. The abundances of the light elements depend almost solely on one key parameter, the baryon-to-photon ratio, η . The nucleosynthesis predictions can be compared with observational determinations of the abundances of the light elements. Consistency between theory and observations leads to a conservative range of

$$5.1 \times 10^{-10} < \eta < 6.5 \times 10^{-10}$$
 (21.54)

 η is related to the fraction of Ω contained in baryons, $\Omega_{\rm b}$

$$\Omega_{\rm b} = 3.66 \times 10^7 \eta \, h^{-2} \,, \tag{21.55}$$

or $10^{10}\eta=274\Omega_{\rm b}h^2$. The WMAP result [24] for $\Omega_{\rm b}h^2$ of 0.0225 ± 0.0006 translates into a value of $\eta=6.16\pm0.15$. This result can be used to 'predict' the light element abundance which can in turn be compared with observation [58]. The resulting D/H abundance is in excellent agreement with that found in quasar absorption systems. It is in reasonable agreement with the helium abundance observed in extra-galactic HII regions (once systematic uncertainties are accounted for), but is in poor agreement with the Li abundance observed in the atmospheres of halo dwarf stars [59]. (See the review on BBN—Sec. 22 of this *Review* for a detailed discussion of BBN or references [60,61].)

21.3.8. The transition to a matter-dominated Universe:

In the Standard Model, the temperature (or redshift) at which the Universe undergoes a transition from a radiation dominated to a matter dominated Universe is determined by the amount of dark matter. Assuming three nearly massless neutrinos, the energy density in radiation at temperatures $T \ll 1$ MeV, is given by

$$\rho_r = \frac{\pi^2}{30} \left[2 + \frac{21}{4} \left(\frac{4}{11} \right)^{4/3} \right] T^4 . \tag{21.56}$$

In the absence of non-baryonic dark matter, the matter density can be written as

$$\rho_m = m_{\rm N} \eta \, n_{\gamma} \,, \tag{21.57}$$

where $m_{\rm N}$ is the nucleon mass. Recalling that $n_{\gamma} \propto T^3$ [cf. Eq. (21.39)], we can solve for the temperature or redshift at the matter-radiation equality when $\rho_r = \rho_m$,

$$T_{eq} = 0.22 \, m_{\rm N} \, \eta$$
 or $(1 + z_{\rm eq}) = 0.22 \, \eta \frac{m_{\rm N}}{T_0}$, (21.58)

where T_0 is the present temperature of the microwave background. For $\eta = 6.2 \times 10^{-10}$, this corresponds to a temperature $T_{\rm eq} \simeq 0.13$ eV or $(1+z_{\rm eq}) \simeq 550$. A transition this late is very problematic for structure formation (see Sec. 21.4.5).

The redshift of matter domination can be pushed back significantly if non-baryonic dark matter is present. If instead of Eq. (21.57), we write

$$\rho_m = \Omega_{\rm m} \rho_c \left(\frac{T}{T_0}\right)^3 \,, \tag{21.59}$$

we find that

$$T_{eq} = 0.9 \frac{\Omega_{\rm m} \rho_c}{T_0^3}$$
 or $(1 + z_{eq}) = 2.4 \times 10^4 \Omega_{\rm m} h^2$. (21.60)

21.4. The Universe at late times

21.4.1. The CMB:

One form of the infamous Olbers' paradox says that, in Euclidean space, surface brightness is independent of distance. Every line of sight will terminate on matter that is hot enough to be ionized and so scatter photons: $T\gtrsim 10^3$ K; the sky should therefore shine as brightly as the surface of the Sun. The reason the night sky is dark is entirely due to the expansion, which cools the radiation temperature to 2.73 K. This gives a Planck function peaking at around 1 mm to produce the microwave background (CMB).

The CMB spectrum is a very accurate match to a Planck function [62]. (See the review on CBR—Sec. 25 of this *Review*.) The COBE estimate of the temperature is [63]

$$T = 2.7255 \pm 0.0006 \,\mathrm{K}$$
 (21.61)

The lack of any distortion of the Planck spectrum is a strong physical constraint. It is very difficult to account for in any expanding universe other than one that passes through a hot stage. Alternative schemes for generating the radiation, such as thermalization of starlight by dust grains, inevitably generate a superposition of temperatures. What is required in addition to thermal equilibrium is that $T \propto 1/R$, so that radiation from different parts of space appears identical.

Although it is common to speak of the CMB as originating at "recombination," a more accurate terminology is the era of "last scattering." In practice, this takes place at $z\simeq 1100$, almost independently of the main cosmological parameters, at which time the fractional ionization is very small. This occurred when the age of the Universe was a few hundred thousand years. (See the review on CBR–Sec. 25 of this Review for a full discussion of the CMB.)

21.4.2. Matter in the Universe:

One of the main tasks of cosmology is to measure the density of the Universe, and how this is divided between dark matter and baryons. The baryons consist partly of stars, with $0.002 \lesssim \Omega_* \lesssim 0.003$ [64] but mainly inhabit the intergalactic medium (IGM). One powerful way in which this can be studied is via the absorption of light from distant luminous objects such as quasars. Even very small amounts of neutral hydrogen can absorb rest-frame UV photons (the Gunn-Peterson effect), and should suppress the continuum by a factor $\exp(-\tau)$, where

$$\tau \simeq 10^{4.62} h^{-1} \left[\frac{n_{\rm HI}(z)/{\rm m}^{-3}}{(1+z)\sqrt{1+\Omega_{\rm m}z}} \right] ,$$
 (21.62)

and this expression applies while the Universe is matter dominated $(z\gtrsim 1$ in the $\Omega_{\rm m}=0.3~\Omega_{\rm v}=0.7$ model). It is possible that this general absorption has now been seen at z=6.2-6.4 [65]. In any case, the dominant effect on the spectrum is a 'forest' of narrow absorption lines, which produce a mean $\tau=1$ in the Ly α forest at about z=3, and so we have $\Omega_{\rm HI}\simeq 10^{-6.7}h^{-1}$. This is such a small number that clearly the IGM is very highly ionized at these redshifts.

The Ly α forest is of great importance in pinning down the abundance of deuterium. Because electrons in deuterium differ in reduced mass by about 1 part in 4000 compared to hydrogen, each absorption system in the Ly α forest is accompanied by an offset deuterium line. By careful selection of systems with an optimal HI column density, a measurement of the D/H ratio can be made. This has now been done in 7 quasars, with relatively consistent results [66]. Combining these determinations with the theory of primordial nucleosynthesis yields a baryon density of $\Omega_{\rm b}h^2=0.019-0.024$ (95% confidence). (See also the review on BBN—Sec. 22 of this Review.)

Ionized IGM can also be detected in emission when it is densely clumped, via bremsstrahlung radiation. This generates the spectacular X-ray emission from rich clusters of galaxies. Studies of this phenomenon allow us to achieve an accounting of the total baryonic material in clusters. Within the central $\simeq 1~\mathrm{Mpc},$ the masses in stars, X-ray emitting gas and total dark matter can be determined with reasonable accuracy (perhaps 20% rms), and this allows a minimum baryon fraction to be determined [67,68]:

$$\frac{M_{\text{baryons}}}{M_{\text{total}}} \gtrsim 0.009 + (0.066 \pm 0.003) \, h^{-3/2} \,.$$
 (21.63)

Because clusters are the largest collapsed structures, it is reasonable to take this as applying to the Universe as a whole. This equation implies a minimum baryon fraction of perhaps 12% (for reasonable h), which is too high for $\Omega_{\rm m}=1$ if we take $\Omega_{\rm b}h^2\simeq 0.02$ from nucleosynthesis. This is therefore one of the more robust arguments in favor of $\Omega_{\rm m}\simeq 0.3$. (See the review on Cosmological Parameters—Sec. 23 of this Review.) This argument is also consistent with the inference on $\Omega_{\rm m}$ that can be made from Fig. 21.2.

This method is much more robust than the older classical technique for weighing the Universe: ' $L \times M/L$.' The overall light density of the Universe is reasonably well determined from redshift surveys of galaxies, so that a good determination of mass M and luminosity L for a single object suffices to determine $\Omega_{\rm m}$ if the mass-to-light ratio is universal.

21.4.3. Gravitational lensing:

A robust method for determining masses in cosmology is to use gravitational light deflection. Most systems can be treated as a geometrically thin gravitational lens, where the light bending is assumed to take place only at a single distance. Simple geometry then determines a mapping between the coordinates in the intrinsic source plane and the observed image plane:

$$\alpha(D_{\rm L}\theta_{\rm I}) = \frac{D_{\rm S}}{D_{\rm LS}}(\theta_{\rm I} - \theta_{\rm S}) , \qquad (21.64)$$

where the angles $\theta_{\rm I}, \theta_{\rm S}$ and α are in general two-dimensional vectors on the sky. The distances $D_{\rm LS}$ etc. are given by an extension of the usual distance-redshift formula:

$$D_{\rm LS} = \frac{R_0 S_k (\chi_{\rm S} - \chi_{\rm L})}{1 + z_{\rm S}} \ . \tag{21.65}$$

This is the angular-diameter distance for objects on the source plane as perceived by an observer on the lens.

Solutions of this equation divide into weak lensing, where the mapping between source plane and image plane is one-to-one, and strong lensing, in which multiple imaging is possible. For circularly-symmetric lenses, an on-axis source is multiply imaged into a 'caustic' ring, whose radius is the Einstein radius:

$$\theta_{\rm E} = \left(4GM \frac{D_{\rm LS}}{D_{\rm L}D_{\rm S}}\right)^{1/2}$$

$$= \left(\frac{M}{10^{11.09} M_{\odot}}\right)^{1/2} \left(\frac{D_{\rm L}D_{\rm S}/D_{\rm LS}}{\rm Gpc}\right)^{-1/2} \quad \text{arcsec} .$$
(21.66)

The observation of 'arcs' (segments of near-perfect Einstein rings) in rich clusters of galaxies has thus given very accurate masses for the central parts of clusters—generally in good agreement with other indicators, such as analysis of X-ray emission from the cluster IGM [69].

Gravitational lensing has also developed into a particularly promising probe of cosmological structure on 10 to 100 Mpc scales. Weak image distortions manifest themselves as an additional ellipticity of galaxy images ('shear'), which can be observed by averaging many images together (the corresponding flux amplification is less readily detected). The result is a 'cosmic shear' field of order 1% ellipticity, coherent over scales of around 30 arcmin, which is directly related to the cosmic mass field, without any astrophysical uncertainties. For this reason, weak lensing is seen as potentially the cleanest probe of matter fluctuations, next to the CMB. Already, impressive results have been obtained in measuring cosmological parameters, based on survey data from only $\sim 50~{\rm deg^2}$ [85]. The particular current strength of this technique is the ability to measure the amplitude of mass fluctuations; this can be deduced from the CMB only subject to uncertainty over the optical depth due to Thomson scattering after reionization.

21.4.4. Density Fluctuations:

The overall properties of the Universe are very close to being homogeneous; and yet telescopes reveal a wealth of detail on scales varying from single galaxies to large-scale structures of size exceeding 100 Mpc. The existence of these structures must be telling us something important about the initial conditions of the Big Bang, and about the physical processes that have operated subsequently. This motivates the study of the density perturbation field, defined as

$$\delta(\mathbf{x}) \equiv \frac{\rho(\mathbf{x}) - \langle \rho \rangle}{\langle \rho \rangle} \ . \tag{21.67}$$

A critical feature of the δ field is that it inhabits a universe that is isotropic and homogeneous in its large-scale properties. This suggests that the statistical properties of δ should also be statistically homogeneous—*i.e.*, it is a stationary random process.

It is often convenient to describe δ as a Fourier superposition:

$$\delta(\mathbf{x}) = \sum \delta_{\mathbf{k}} e^{-i\mathbf{k} \cdot \mathbf{x}} \ . \tag{21.68}$$

We avoid difficulties with an infinite universe by applying periodic boundary conditions in a cube of some large volume V. The crossterms vanish when we compute the variance in the field, which is just a sum over modes of the power spectrum

$$\langle \delta^2 \rangle = \sum |\delta_{\mathbf{k}}|^2 \equiv \sum P(k) .$$
 (21.69)

Note that the statistical nature of the fluctuations must be isotropic, so we write P(k) rather than $P(\mathbf{k})$. The $\langle \ldots \rangle$ average here is a volume average. Cosmological density fields are an example of an ergodic process, in which the average over a large volume tends to the same answer as the average over a statistical ensemble.

The statistical properties of discrete objects sampled from the density field are often described in terms of N-point correlation functions, which represent the excess probability over random for finding one particle in each of N boxes in a given configuration. For the 2-point case, the correlation function is readily shown to be identical to the autocorrelation function of the δ field: $\xi(r) = \langle \delta(x)\delta(x+r) \rangle$.

The power spectrum and correlation function are Fourier conjugates, and thus are equivalent descriptions of the density field (similarly, k-space equivalents exist for the higher-order correlations). It is convenient to take the limit $V \to \infty$ and use k-space integrals, defining a dimensionless power spectrum, which measures the contribution to the fractional variance in density per unit logarithmic range of scale, as $\Delta^2(k) = d\langle \delta^2 \rangle/d \ln k = V k^3 P(k)/2\pi^2$:

$$\xi(r) = \int \Delta^2(k) \, \frac{\sin kr}{kr} \, d \ln k; \quad \Delta^2(k) = \frac{2}{\pi} k^3 \int_0^\infty \xi(r) \, \frac{\sin kr}{kr} \, r^2 \, dr \; . \eqno(21.70)$$

For many years, an adequate approximation to observational data on galaxies was $\xi = (r/r_0)^{-\gamma}$, with $\gamma \simeq 1.8$ and $r_0 \simeq 5\,h^{-1}\,{\rm Mpc}$. Modern surveys are now able to probe into the large-scale linear regime where unaltered traces of the curved post-recombination spectrum can be detected [70,71,72].

${\bf 21.4.5.} \quad Formation \ of \ cosmological \ structure:$

The simplest model for the generation of cosmological structure is gravitational instability acting on some small initial fluctuations (for the origin of which a theory such as inflation is required). If the perturbations are adiabatic (*i.e.*, fractionally perturb number densities of photons and matter equally), the linear growth law for matter perturbations is simple:

$$\delta \propto \begin{cases} a^2(t) & \text{(radiation domination; } \Omega_{\rm r} = 1) \\ a(t) & \text{(matter domination; } \Omega_{\rm m} = 1) \end{cases} . \tag{21.71}$$

For low density universes, the present-day amplitude is suppressed by a factor $q(\Omega)$, where

$$g(\Omega) \simeq \frac{5}{2}\Omega_{\rm m} \left[\Omega_{\rm m}^{4/7} - \Omega_{\rm v} + (1 + \Omega_{\rm m}/2)(1 + \frac{1}{70}\Omega_{\rm v})\right]^{-1}$$
 (21.72)

is an accurate fit for models with matter plus cosmological constant. The alternative perturbation mode is isocurvature: only the equation of state changes, and the total density is initially unperturbed. These modes perturb the total entropy density, and thus induce additional large-scale CMB anisotropies [73]. Although the character of perturbations in the simplest inflationary theories are purely adiabatic, correlated adiabatic and isocurvature modes are predicted in many models; the simplest example is the curvaton, which is a scalar field that decays to yield a perturbed radiation density. If the matter content already exists at this time, the overall perturbation field will have a significant isocurvature component. Such a prediction is inconsistent with current CMB data [74], and most analyses of CMB and LSS data assume the adiabatic case to hold exactly.

Linear evolution preserves the shape of the power spectrum. However, a variety of processes mean that growth actually depends on the matter content:

(1) Pressure opposes gravity effectively for wavelengths below the horizon length while the Universe is radiation dominated. The comoving horizon size at z_{eq} is therefore an important scale:

$$D_{\rm H}(z_{\rm eq}) = \frac{2(\sqrt{2} - 1)}{(\Omega_{\rm m} z_{\rm eq})^{1/2} H_0} = \frac{16.0}{\Omega_{\rm m} h^2} {\rm Mpc} \ .$$
 (21.73)

- (2) At early times, dark matter particles will undergo free streaming at the speed of light, and so erase all scales up to the horizon—a process that only ceases when the particles go nonrelativistic. For light massive neutrinos, this happens at z_{eq}; all structure up to the horizon-scale power-spectrum break is in fact erased. Hot(cold) dark matter models are thus sometimes dubbed large(small)-scale damping models.
- (3) A further important scale arises where photon diffusion can erase perturbations in the matter–radiation fluid; this process is named Silk damping.

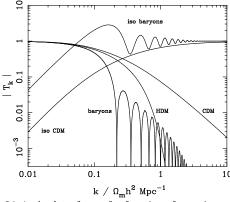

Figure 21.4: A plot of transfer functions for various models. For adiabatic models, $T_k \to 1$ at small k, whereas the opposite is true for isocurvature models. For dark-matter models, the characteristic wavenumber scales proportional to $\Omega_{\rm m}h^2$. The scaling for baryonic models does not obey this exactly; the plotted cases correspond to $\Omega_{\rm m}=1,\,h=0.5$.

The overall effect is encapsulated in the transfer function, which gives the ratio of the late-time amplitude of a mode to its initial value (see Fig. 21.4). The overall power spectrum is thus the primordial power-law, times the square of the transfer function:

$$P(k) \propto k^n T_k^2 \ . \tag{21.74}$$

The most generic power-law index is n=1: the 'Zeldovich' or 'scale-invariant' spectrum. Inflationary models tend to predict a small 'tilt:' $|n-1|\lesssim 0.03$ [12,13]. On the assumption that the dark matter is cold, the power spectrum then depends on 5 parameters: $n, h, \Omega_{\rm b}, \Omega_{\rm cdm} \ (\equiv \Omega_{\rm m} - \Omega_{\rm b})$ and an overall amplitude. The latter is often specified as σ_8 , the linear-theory fractional rms in density when a spherical filter of radius $8\,h^{-1}$ Mpc is applied in linear theory. This

scale can be probed directly via weak gravitational lensing, and also via its effect on the abundance of rich galaxy clusters. The favored value is approximately [34,75]

$$\sigma_8 \simeq (0.803 \pm 0.011) (\Omega_{\rm m}/0.25)^{-0.47}$$
. (21.75)

A direct measure of mass inhomogeneity is valuable, since the galaxies inevitably are biased with respect to the mass. This means that the fractional fluctuations in galaxy number, $\delta n/n$, may differ from the mass fluctuations, $\delta \rho/\rho$. It is commonly assumed that the two fields obey some proportionality on large scales where the fluctuations are small, $\delta n/n = b\delta \rho/\rho$, but even this is not guaranteed [76].

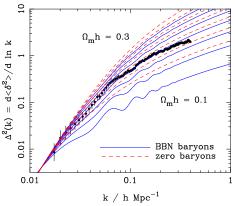

Figure 21.5: The galaxy power spectrum from the 2dFGRS [71], shown in dimensionless form, $\Delta^2(k) \propto k^3 P(k)$. The solid points with error bars show the power estimate. The window function correlates the results at different k values, and also distorts the large-scale shape of the power spectrum An approximate correction for the latter effect has been applied. The solid and dashed lines show various CDM models, all assuming n=1. For the case with non-negligible baryon content, a big-bang nucleosynthesis value of $\Omega_{\rm b}h^2=0.02$ is assumed, together with h=0.7. A good fit is clearly obtained for $\Omega_{\rm m}h\simeq0.2$.

The main shape of the transfer function is a break around the horizon scale at $z_{\rm eq}$, which depends just on $\Omega_{\rm m}h$ when wavenumbers are measured in observable units ($h\,{\rm Mpc^{-1}}$). For reasonable baryon content, weak oscillations in the transfer function are also expected, and these BAOs (Baryon Acoustic Oscillations) have been clearly detected [77,78]. As well as directly measuring the baryon fraction, the scale of the oscillations directly measures the acoustic horizon at decoupling; this can be used as an additional standard ruler for cosmological tests, and the BAO method is likely to be important in future large galaxy surveys. Overall, current power-spectrum data [70,71,72] favor $\Omega_{\rm m}h\simeq 0.20$ and a baryon fraction of about 0.15 for n=1 (see Fig. 21.5).

In principle, accurate data over a wide range of k could determine both Ωh and n, but in practice there is a strong degeneracy between these. In order to constrain n itself, it is necessary to examine data on anisotropies in the CMB.

${\bf 21.4.6.} \quad CMB \ anisotropies:$

The CMB has a clear dipole anisotropy, of magnitude 1.23×10^{-3} . This is interpreted as being due to the Earth's motion, which is equivalent to a peculiar velocity for the Milky Way of

$$v_{\rm MW} \simeq 600 \,\rm km \, s^{-1} \quad towards \quad (\ell, b) \simeq (270^{\circ}, 30^{\circ}) \; .$$
 (21.76)

All higher-order multipole moments of the CMB are however much smaller (of order 10^{-5}), and interpreted as signatures of density fluctuations at last scattering ($\simeq 1100$). To analyze these, the sky is expanded in spherical harmonics as explained in the review on CBR–Sec. 25 of this *Review*. The dimensionless power per $\ln k$ or 'bandpower' for the CMB is defined as

$$\mathcal{T}^{2}(\ell) = \frac{\ell(\ell+1)}{2\pi} C_{\ell} . \tag{21.77}$$

This function encodes information from the three distinct mechanisms that cause CMB anisotropies:

- Gravitational (Sachs-Wolfe) perturbations. Photons from highdensity regions at last scattering have to climb out of potential wells, and are thus redshifted.
- (2) Intrinsic (adiabatic) perturbations. In high-density regions, the coupling of matter and radiation can compress the radiation also, giving a higher temperature.
- (3) Velocity (Doppler) perturbations. The plasma has a non-zero velocity at recombination, which leads to Doppler shifts in frequency and hence shifts in brightness temperature.

Because the potential fluctuations obey Poisson's equation, $\nabla^2 \Phi = 4\pi G \rho \delta$, and the velocity field satisfies the continuity equation $\nabla \cdot \mathbf{u} = -\dot{\delta}$, the resulting different powers of k ensure that the Sachs-Wolfe effect dominates on large scales and adiabatic effects on small scales.

The relation between angle and comoving distance on the last-scattering sphere requires the comoving angular-diameter distance to the last-scattering sphere; because of its high redshift, this is effectively identical to the horizon size at the present epoch, $D_{\rm H}$:

$$\begin{split} D_{\rm H} &= \frac{2}{\Omega_{\rm m} H_0} \quad (\Omega_{\rm v} = 0) \\ D_{\rm H} &\simeq \frac{2}{\Omega_{\rm m}^{0.4} H_0} \quad ({\rm flat}: \Omega_{\rm m} + \Omega_{\rm v} = 1) \; . \end{split} \tag{21.78}$$

These relations show how the CMB is strongly sensitive to curvature: the horizon length at last scattering is $\propto 1/\sqrt{\Omega_m}$, so that this subtends an angle that is virtually independent of Ω_m for a flat model. Observations of a peak in the CMB power spectrum at relatively large scales ($\ell \simeq 225$) are thus strongly inconsistent with zero- Λ models with low density: current CMB + BAO +SN data require $\Omega_m + \Omega_v = 1.006 \pm 0.007$ [24]. (See e.g., Fig. 21.2).

In addition to curvature, the CMB encodes information about several other key cosmological parameters. Within the compass of simple adiabatic CDM models, there are 9 of these:

$$\omega_c, \ \omega_b, \ \Omega_t, \ h, \ \tau, \ n_s, \ n_t, \ r, \ Q \ .$$
 (21.79)

The symbol ω denotes the physical density, Ωh^2 : the transfer function depends only on the densities of CDM (ω_c) and baryons (ω_b). Transcribing the power spectrum at last scattering into an angular power spectrum brings in the total density parameter ($\Omega_t \equiv \Omega_{\rm m} + \Omega_{\rm v} = \Omega_c + \Omega_{\rm b} + \Omega_{\rm v}$) and h: there is an exact geometrical degeneracy [79] between these that keeps the angular-diameter distance to last scattering invariant, so that models with substantial spatial curvature and large vacuum energy cannot be ruled out without prior knowledge of the Hubble parameter. Alternatively, the CMB alone cannot measure the Hubble parameter.

The other main parameter degeneracy involves the tensor contribution to the CMB anisotropies. These are important at large scales (up to the horizon scales); for smaller scales, only scalar fluctuations (density perturbations) are important. Each of these components is characterized by a spectral index, n, and a ratio between the power spectra of tensors and scalars (r). See the review on Cosmological Parameters—Sec. 23 of this Review for a technical definition of the r parameter. Finally, the overall amplitude of the spectrum must be specified (Q), together with the optical depth to Compton scattering owing to recent reionization (τ) . The tensor degeneracy operates as follows: the main effect of adding a large tensor contribution is to reduce the contrast between low ℓ and the peak at $\ell \simeq 225$ (because the tensor spectrum has no acoustic component). The required height of the peak can be recovered by increasing n_s to increase the small-scale power in the scalar component; this in turn over-predicts the power at $\ell \sim 1000$, but this effect can be counteracted by raising the baryon density [80]. In order to break this degeneracy, additional data are required. For example, an excellent fit to the CMB data is obtained with a scalar-only model with zero curvature and $\omega_{\rm b} = 0.0225, \, \omega_{\rm c} = 0.1120, \, h = 0.704, \, n_{\rm s} = 0.967 \, [24].$ However, this is indistinguishable from a model where tensors dominate at $\ell \lesssim 100$,

if we raise $\omega_{\rm b}$ to 0.03 and $n_{\rm s}$ to 1.2. This baryon density is too high for nucleosynthesis, which disfavors the high-tensor solution [81].

The reason the tensor component is introduced, and why it is so important, is that it is the only non-generic prediction of inflation. Slow-roll models of inflation involve two dimensionless parameters:

$$\epsilon \equiv \frac{M_{\rm P}^2}{16\pi} \left(\frac{V'}{V}\right)^2 \qquad \eta \equiv \frac{M_{\rm P}^2}{8\pi} \left(\frac{V''}{V}\right) , \qquad (21.80)$$

where V is the inflaton potential, and dashes denote derivatives with respect to the inflation field. In terms of these, the tensor-to-scalar ratio is $r \simeq 16\epsilon$, and the spectral indices are $n_s = 1 - 6\epsilon + 2\eta$ and $n_{\rm t}=-2\epsilon$. The natural expectation of inflation is that the quasi-exponential phase ends once the slow-roll parameters become significantly non-zero, so that both $n_s \neq 1$ and a significant tensor component are expected. These prediction can be avoided in some models, but it is undeniable that observation of such features would be a great triumph for inflation. Cosmology therefore stands at a fascinating point given that the most recent CMB data appear to reject the zero-tensor $n_s = 1$ model at around 2.4σ : $n_s = 0.967 \pm 0.014$ [24]. If we insist on $n_s = 1$, then a very substantial tensor fraction would be required $(r \simeq 0.2)$, although the fit is better with r = 0. Assuming that no systematic error in this result can be identified, cosmology has passed a critical hurdle; the years ahead will be devoted to the task of breaking the tensor degeneracy — for which the main tool will be the polarization of the CMB [14].

21.4.7. Probing dark energy and the nature of gravity:

The most radical element of our current cosmological model is the dark energy that accelerates the expansion. The energy density of this component is approximately $(2.4\,\mathrm{meV})^4$ (for w=-1, $\Omega_v=0.75$, h=0.73), or roughly $10^{-123}M_\mathrm{P}^4$, and such an un-naturally small number is hard to understand. Various quantum effects (most simply zero-point energy) should make contributions to the vacuum energy density: these may be truncated by new physics at high energy, but this presumably occurs at $>1\,\mathrm{TeV}$ scales, not meV; thus the apparent energy scale of the vacuum is at least 10^{15} times smaller than its natural value. This situation is well analysed in [82], which lists extreme escape routes – especially the multiverse viewpoint, according to which low values of Λ are rare, but high values suppress the formation of structure and observers. It is certainly impressive that Weinberg used such reasoning to predict the value of Λ before any data strongly indicated a non-zero value.

But it may be that the phenomenon of dark energy is entirely illusory. The necessity for this constituent arises from using the Friedmann equation to describe the evolution of the cosmic expansion; if this equation is incorrect, it would require the replacement of Einstein's relativistic theory of gravity with some new alternative. A frontier of current cosmological research is to distinguish these possibilities [87,88]. We also note that it has been suggested that dark energy might be an illusion even within general relativity, owing to an incorrect treatment of averaging in an inhomogeneous Universe [89,90]. Many would argue that a standard Newtonian treatment of such issues should be adequate inside the cosmological horizon, but debate on this issue continues.

Dark Energy can differ from a classical cosmological constant in being a dynamical phenomenon [33,91], e.g., a rolling scalar field (sometimes dubbed 'quintessence'). Empirically, this means that it is endowed with two thermodynamic properties that astronomers can try to measure: the bulk equation of state and the sound speed. If the sound speed is close to the speed of light, the effect of this property is confined to very large scales, and mainly manifests itself in the large-angle multipoles of the CMB anisotropies [92]. The equation of state parameter governs the rate of change of the vacuum density: $d \ln \rho_v / d \ln a = -3(1+w)$, so it can be accessed via the evolving expansion rate, H(a). This can be measured most cleanly by using the inbuilt natural ruler of large-scale structure: the Baryon Acoustic Oscillation horizon scale [93]:

$$D_{\rm BAO} \simeq 147 \, (\Omega_{\rm m} h^2 / 0.13)^{-0.25} (\Omega_{\rm b} h^2 / 0.023)^{-0.08} \,{\rm Mpc} \,.$$
 (21.81)

H(a) is measured by radial clustering, since dr/dz = c/H; clustering in the plane of the sky measures the integral of this. The expansion

rate is also measured by the growth of density fluctuations, where the pressure-free growth equation for the density perturbation is $\ddot{\delta} + 2H(a)\dot{\delta} = 4\pi G\rho_0 \delta$. Thus, both the scale and amplitude of density fluctuations are sensitive to w(a) – but only weakly. These observables change by only typically 0.2% for a 1% change in w. Current constraints [24] are -1.11 < w < -0.89 (95% confidence), so a substantial improvement will require us to limit systematics in data to a few parts in 1000.

Testing whether theories of gravity require revision can also be done using data on cosmological inhomogeneities. Two separate issues arise, concerning the metric perturbation potentials Ψ and Φ , which affect respectively the time and space parts of the metric. In Einstein gravity, these potentials are both equal to the Newtonian gravitational potential, which satisfies Poisson's equation: $\nabla^2 \Phi / a^2 = 4\pi G \bar{\rho} \delta$. Empirically, modifications of gravity require us to explore a change with scale and with time of the 'slip' (Ψ/Φ) and the effective G on the rhs of the Poisson equation. The former aspect can only be probed via gravitational lensing, whereas the latter can be addressed on 10-100 Mpc scales via the growth of clustering. Various schemes for parameterising modified gravity exist, but a practical approach is to assume that the growth rate can be tied to the density parameter: $d \ln \delta / d \ln a = \Omega_{\rm m}^{\gamma}(a)$ [94]. The parameter γ is close to 0.55 for standard relativistic gravity, but can differ by around 0.1 from this value in many non-standard models. Clearly this parameterization is incomplete, since it explicitly rejects the possibility of early dark energy $(\Omega_{\rm m}(a) \to 1 \text{ as } a \to 0)$, but it is a convenient way of capturing the power of various experiments. Current data are consistent with standard Λ CDM [86], and exclude variations in slip or effective G of larger than a few times 10%.

Current planning envisages a set of satellite probes that, a decade hence, will pursue these fundamental tests via gravitational lensing measurements over thousands of square degrees, $> 10^8$ redshifts, and photometry of > 1000 supernovae (WFIRST in the USA, Euclid in Europe) [22,23]. These experiments will measure both w and the perturbation growth rate to an accuracy of around 1%. The outcome will be either a validation of the standard relativistic vacuum-dominated big bang cosmology at a level of precision far beyond anything attempted to date, or the opening of entirely new directions in cosmological models.

22. BIG-BANG NUCLEOSYNTHESIS

Revised August 2011 by B.D. Fields (Univ. of Illinois) and S. Sarkar (Univ. of Oxford).

Big-Bang nucleosynthesis (BBN) offers the deepest reliable probe of the early Universe, being based on well-understood Standard Model physics [1–8]. Predictions of the abundances of the light elements, D, 3 He, 4 He, and 7 Li, synthesized at the end of the 'first three minutes', are in good overall agreement with the primordial abundances inferred from observational data, thus validating the standard hot Big-Bang cosmology (see [9] for a review). This is particularly impressive given that these abundances span nine orders of magnitude – from 4 He/H ~ 0.08 down to 7 Li/H $\sim 10^{-10}$ (ratios by number). Thus BBN provides powerful constraints on possible deviations from the standard cosmology, and on new physics beyond the Standard Model [4–7].

22.1. Theory

The synthesis of the light elements is sensitive to physical conditions in the early radiation-dominated era at a temperature $T \sim 1$ MeV, corresponding to an age $t \sim 1$ s. At higher temperatures, weak interactions were in thermal equilibrium, thus fixing the ratio of the neutron and proton number densities to be $n/p = e^{-Q/T}$, where Q = 1.293 MeV is the neutron-proton mass difference. As the temperature dropped, the neutron-proton inter-conversion rate, $\Gamma_{n \leftarrow p} \sim G_{\rm F}^2 T^5$, fell faster than the Hubble expansion rate, $H \sim \sqrt{g_* G_N} T^2$, where g_* counts the number of relativistic particle species determining the energy density in radiation (see 'Big Bang Cosmology' review). This resulted in departure from chemical equilibrium ('freeze-out') at $T_{\rm fr} \sim (g_* G_{\rm N}/G_{\rm F}^4)^{1/6} \simeq 1$ MeV. The neutron fraction at this time, $n/p = e^{-Q/T_{\rm fr}} \simeq 1/6$, is thus sensitive to every known physical interaction, since Q is determined by both strong and electromagnetic interactions while $T_{\rm fr}$ depends on the weak as well as gravitational interactions. Moreover, the sensitivity to the Hubble expansion rate affords a probe of e.g., the number of relativistic neutrino species [10]. After freeze-out, the neutrons were free to β -decay, so the neutron fraction dropped to $n/p \simeq 1/7$ by the time nuclear reactions began. A simplified analytic model of freeze-out yields the n/p ratio to an accuracy of $\sim 1\%$ [11,12].

The rates of these reactions depend on the density of baryons (strictly speaking, nucleons), which is usually expressed normalized to the relic blackbody photon density as $\eta \equiv n_{\rm b}/n_{\gamma}$. As we shall see, all the light-element abundances can be explained with $\eta_{10} \equiv \eta \times 10^{10}$ in the range 5.1–6.5 (95% CL). With n_{γ} fixed by the present CMB temperature 2.725 K (see 'Cosmic Microwave Background' review), this can be stated as the allowed range for the baryon mass density today, $\rho_{\rm b} = (3.5-4.5) \times 10^{-31}~{\rm g\,cm}^{-3}$, or as the baryonic fraction of the critical density, $\Omega_{\rm b} = \rho_{\rm b}/\rho_{\rm crit} \simeq \eta_{10}h^{-2}/274 = (0.019-0.024)h^{-2}$, where $h \equiv H_0/100~{\rm km\,s}^{-1}~{\rm Mpc}^{-1} = 0.72 \pm 0.08$ is the present Hubble parameter (see Cosmological Parameters review).

The nucleosynthesis chain begins with the formation of deuterium in the process $p(n,\gamma)$ D. However, photo-dissociation by the high number density of photons delays production of deuterium (and other complex nuclei) well after T drops below the binding energy of deuterium, $\Delta_{\rm D}=2.23$ MeV. The quantity $\eta^{-1}{\rm e}^{-\Delta_{\rm D}/T}$, i.e., the number of photons per baryon above the deuterium photo-dissociation threshold, falls below unity at $T\simeq 0.1$ MeV; nuclei can then begin to form without being immediately photo-dissociated again. Only 2-body reactions, such as ${\rm D}(p,\gamma)^3{\rm He}$, $^3{\rm He}({\rm D},p)^4{\rm He}$, are important because the density by this time has become rather low – comparable to that of air!

Nearly all neutrons end up bound in the most stable light element $^4\mathrm{He}$. Heavier nuclei do not form in any significant quantity both because of the absence of stable nuclei with mass number 5 or 8 (which impedes nucleosynthesis via $n^4\mathrm{He}$, $p^4\mathrm{He}$ or $^4\mathrm{He}^4\mathrm{He}$ reactions), and the large Coulomb barriers for reactions such as $^3\mathrm{He}(^4\mathrm{He},\gamma)^7\mathrm{Li}$ and $^3\mathrm{He}(^4\mathrm{He},\gamma)^7\mathrm{Be}$. Hence the primordial mass fraction of $^4\mathrm{He}$, conventionally referred to as Y_p , can be estimated by the simple counting argument

$$Y_{\rm p} = \frac{2(n/p)}{1 + n/p} \simeq 0.25 \ .$$
 (22.1)

There is little sensitivity here to the actual nuclear reaction rates, which are, however, important in determining the other 'left-over'

abundances: D and 3 He at the level of a few times 10^{-5} by number relative to H, and 7 Li/H at the level of about 10^{-10} (when η_{10} is in the range 1–10). These values can be understood in terms of approximate analytic arguments [12,13]. The experimental parameter most important in determining $Y_{\rm p}$ is the neutron lifetime, τ_n , which normalizes (the inverse of) $\Gamma_{n\!-\!p}$. The experimental uncertainty in τ_n has been thought small, at $\tau_n=885.7\pm0.8$ s but recent measurements and re-analyses suggest possible systematic errors ~ 6 times larger (see N Baryons Listing).

The elemental abundances shown in Fig. 22.1 as a function of η_{10} were calculated [14] using an updated version [15] of the Wagoner code [1]; other modern versions [16,17] are publicly available. The ⁴He curve includes small corrections due to radiative processes at zero and finite temperatures [18], non-equilibrium neutrino heating during e^{\pm} annihilation [19], and finite nucleon mass effects [20]; the range reflects primarily the 2σ uncertainty in the neutron lifetime. The spread in the curves for D, ³He, and ⁷Li corresponds to the 2σ uncertainties in nuclear cross sections, as estimated by Monte Carlo methods [21–22]. The input nuclear data have been carefully reassessed [14, 23-27], leading to improved precision in the abundance predictions. In particular, the uncertainty in ⁷Li/H at interesting values of η has been reduced recently by a factor ~ 2 , a consequence of a similar reduction in the error budget [28] for the dominant mass-7 production channel ${}^{3}\text{He}({}^{4}\text{He},\gamma){}^{7}\text{Be}$. Polynomial fits to the predicted abundances and the error correlation matrix have been given [22,29]. The boxes in Fig. 22.1 show the observationally inferred primordial abundances with their associated statistical and systematic uncertainties, as discussed below.

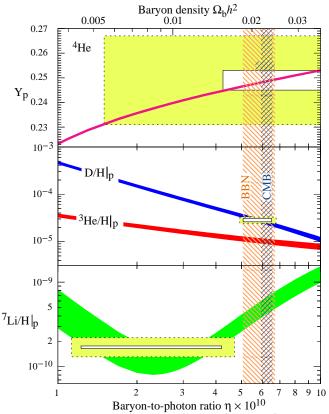

Figure 22.1: The abundances of ^4He , D, ^3He , and ^7Li as predicted by the standard model of Big-Bang nucleosynthesis [14] — the bands show the 95% CL range. Boxes indicate the observed light element abundances (smaller boxes: $\pm 2\sigma$ statistical errors; larger boxes: $\pm 2\sigma$ statistical and systematic errors). The narrow vertical band indicates the CMB measure of the cosmic baryon density, while the wider band indicates the BBN concordance range (both at 95% CL).

22.2. Light Element Abundances

BBN theory predicts the universal abundances of D, $^3\mathrm{He},^4\mathrm{He},$ and $^7\mathrm{Li},$ which are essentially fixed by $t\sim180\,\mathrm{s}.$ Abundances are, however, usually observed at much later epochs, after stellar nucleosynthesis has commenced. The ejected remains of this stellar processing can alter the light element abundances from their primordial values, and also produce heavy elements such as C, N, O, and Fe ('metals'). Thus, one seeks astrophysical sites with low metal abundances, in order to measure light element abundances which are closer to primordial. For all of the light elements, systematic errors are an important (and often dominant) limitation to the precision with which primordial abundances can be inferred.

High-resolution spectra reveal the presence of D in high-redshift, low-metallicity quasar absorption systems via its isotope-shifted Lyman-α absorption [30–33]. It is believed that there are no astrophysical sources of deuterium [34], so any detection provides a lower limit to primordial D/H, and thus an upper limit on η ; for example, the local interstellar value of D/H|_p = $(1.56\pm0.04)\times10^{-5}$ [35] requires $\eta_{10} \leq 9$. Recent observations find an unexpected scatter of a factor of ~ 2 [36], as well as correlations with heavy element abundances which suggest that interstellar D may suffer stellar processing (astration), but also partly reside in dust particles which evade gas-phase observations. This is supported by a measurement in the lower halo [37], which indicates that the Galactic D abundance has been reduced by a factor of only 1.12±0.13 since its formation. For the high-redshift systems, conventional models of galactic nucleosynthesis (chemical evolution) do not predict either of these effects for D/H [38].

The observed extragalactic D values are bracketed by the non-detection of D in a high-redshift system, $\mathrm{D/H|_p} < 6.7 \times 10^{-5}$ at 1σ [39], and low values in some (damped Lyman- α) systems [30,31]. Averaging the seven most precise observations of deuterium in quasar absorption systems gives $\mathrm{D/H} = (2.82 \pm 0.12) \times 10^{-5}$, where the error is statistical only [32,33]. However, there remains concern over systematic errors, the dispersion between the values being much larger than is expected from the individual measurement errors ($\chi^2 = 17.7$ for $\nu = 6$ d.o.f.). Increasing the error by a factor $\sqrt{\chi^2/\nu}$ gives, as shown in Fig. 22.1:

$$D/H|_{p} = (2.82 \pm 0.21) \times 10^{-5}.$$
 (22.2)

⁴He can be observed in clouds of ionized hydrogen (H II regions), the most metal-poor of which are in dwarf galaxies. There is now a large body of data on ⁴He and CNO in such systems [40]. These data confirm that the small stellar contribution to helium is positively correlated with metal production. Extrapolating to zero metallicity gives the primordial ⁴He abundance [41]

$$Y_{\rm p} = 0.249 \pm 0.009.$$
 (22.3)

Here the latter error is a careful (and significantly enlarged) estimate of the systematic uncertainties which dominate, and is based on the scatter in different analyses of the physical properties of the H II regions [40,41]. Other recent extrapolations to zero metallicity give $Y_{\rm p}=0.247\pm0.001$ or 0.252 ± 0.001 depending on which set of He I emissivities are used [42], and $Y_{\rm p}=0.248\pm0.003$ [43]. These are consistent (given the systematic errors) with the above estimate [41], which appears in Fig. 22.1. The CMB damping tail (see Cosmic Microwave Background review) is sensitive to the primordial ⁴He abundance [44]. Recent measurements find $Y_{\rm p}=0.296\pm0.030$ [45], consistent with the above; future Planck measurements should tighten this result.

As we will see in more detail below, the primordial abundance of lithium now plays a central role in BBN, and possibly points to new physics. The systems best suited for Li observations are metal-poor stars in the spheroid (Pop II) of our Galaxy, which have metallicities going down to at least 10^{-4} , and perhaps 10^{-5} of the Solar value [46]. Observations have long shown [47–51] that Li does not vary significantly in Pop IIstars with metallicities $\lesssim 1/30$ of Solar — the 'Spite plateau' [47]. Precision data suggest a small but significant correlation between Li and Fe [48], which

can be understood as the result of Li production from Galactic cosmic rays [49]. Extrapolating to zero metallicity, one arrives at a primordial value Li/H|_p = $(1.23 \pm 0.06^{+0.68}_{-0.32}) \times 10^{-10}$ [50], where the first error given is statistical and is very small due to the relatively large sample of 22 stars used. One source of systematic error stems from the differences in techniques used to determine the physical parameters (e.g., the temperature) of the stellar atmosphere in which the Li absorption line is formed. Alternative analyses, using methods that give systematically higher temperatures, and in some cases different stars and stellar systems (globular clusters), yield ${\rm Li/H|_p} = (2.19 \pm 0.28) \times 10^{-10} \, [51], \ {\rm Li/H|_p} = (2.34 \pm 0.32) \times 10^{-10} \, [52],$ and ${\rm Li/H|_p} = (1.26 \pm 0.26) \times 10^{-10} \, [53];$ the differences with [50] indicate a systematic uncertainty of a factor of ~ 2 . Moreover, it is possible that the Li in Pop II stars has been partially destroyed, due to mixing of the outer layers with the hotter interior [54]. Such processes can be constrained by the absence of significant scatter in Li versus Fe [48], and by observations of the fragile isotope ⁶Li [49]. Nevertheless, some depletion is likely to exist: a factor as large as ~ 1.8 has been suggested [55](and recent observations find a puzzling drop in Li/H in ultra-metal-poor stars [56]) . Including these systematics, we estimate a primordial Li range which spans the ranges above, as shown in Fig. 22.1:

$$\text{Li/H}|_{\text{p}} = (1.7 \pm 0.06 \pm 0.44) \times 10^{-10}.$$
 (22.4)

Stellar determination of Li abundances typically sum over both stable isotopes $^6\mathrm{Li}$ and $^7\mathrm{Li}$. Recent high-precision measurements are sensitive to the tiny isotopic shift in Li absorption (which manifests itself in the shape of the blended, thermally broadened line) and indicate $^6\mathrm{Li}/^7\mathrm{Li} \leq 0.15$ [57]. This confirms that $^7\mathrm{Li}$ is dominant, but surprisingly there is indication of a $^6\mathrm{Li}$ plateau (analogous to the $^7\mathrm{Li}$ plateau) which suggests a significant primordial $^6\mathrm{Li}$ abundance. However, caution must be exercised since convective motions in the star can generate similar asymmetries in the line shape, hence the deduced $^6\mathrm{Li}$ abundance is presently best interpreted as an upper limit [58].

Turning to ³He, the only data available are from the Solar system and (high-metallicity) H II regions in our Galaxy [59]. This makes inferring the primordial abundance difficult, a problem compounded by the fact that stellar nucleosynthesis models for ³He are in conflict with observations [60]. Consequently, it is no longer appropriate to use ³He as a cosmological probe; instead, one might hope to turn the problem around and constrain stellar astrophysics using the predicted primordial ³He abundance [61].

22.3. Concordance, Dark Matter, and the CMB

We now use the observed light element abundances to test the theory. We first consider standard BBN, which is based on Standard Model physics alone, so $N_{\nu}=3$ and the only free parameter is the baryon-to-photon ratio η . (The implications of BBN for physics beyond the Standard Model will be considered below, §4). Thus, any abundance measurement determines η , while additional measurements overconstrain the theory and thereby provide a consistency check.

First we note that the overlap in the η ranges spanned by the larger boxes in Fig. 22.1 indicates overall concordance. More quantitatively, when we account for theoretical uncertainties, as well as the statistical and systematic errors in observations, there is acceptable agreement among the abundances when

$$5.1 \le \eta_{10} \le 6.5 \text{ (95\% CL)}.$$
 (22.5)

However, the agreement is much less satisfactory if we use only the quoted statistical errors in the observations. In particular, as seen in Fig. 22.1, D and $^4{\rm He}$ are consistent with each other, but favor a value of η which is higher by a factor of at least 2.4, and by at least $\sim 4.2\sigma$ from that indicated by the $^7{\rm Li}$ abundance determined in stars. Furthermore, if the $^6{\rm Li}$ plateau [57] reflects a primordial component, it is ~ 1000 times that expected in standard BBN; both these "lithium problems" may indicate new physics (see below).

Even so, the overall concordance is remarkable: using well-established microphysics we have extrapolated back to an age of $\sim 1~\rm s$

to correctly predict light element abundances spanning 9 orders of magnitude. This is a major success for the standard cosmology, and inspires confidence in extrapolation back to still earlier times.

This concordance provides a measure of the baryon content

$$0.019 \le \Omega_{\rm b} h^2 \le 0.024 \ (95\% \ {\rm CL}),$$
 (22.6)

a result that plays a key role in our understanding of the matter budget of the Universe. First we note that $\Omega_{\rm b} \ll 1,~i.e.,$ baryons cannot close the Universe [62]. Furthermore, the cosmic density of (optically) luminous matter is $\Omega_{\rm lum} \simeq 0.0024h^{-1}$ [63], so that $\Omega_{\rm b} \gg \Omega_{\rm lum}:$ most baryons are optically dark, probably in the form of a diffuse intergalactic medium [64]. Finally, given that $\Omega_{\rm m} \sim 0.3$ (see Dark Matter and Cosmological Parameters reviews), we infer that most matter in the Universe is not only dark, but also takes some non-baryonic (more precisely, non-nucleonic) form.

The BBN prediction for the cosmic baryon density can be tested through precision observations of CMB temperature fluctuations (see Cosmic Microwave Background review). One can determine η from the amplitudes of the acoustic peaks in the CMB angular power spectrum [65], making it possible to compare two measures of η using very different physics, at two widely separated epochs. In the standard cosmology, there is no change in η between BBN and CMB decoupling, thus, a comparison of $\eta_{\rm BBN}$ and $\eta_{\rm CMB}$ is a key test. Agreement would endorse the standard picture while disagreement could point to new physics during/between the BBN and CMB epochs.

The release of the WMAP results was a landmark event in this test of BBN. As with other cosmological parameter determinations from CMB data, the derived $\eta_{\rm CMB}$ depends on the adopted priors [66], in particular the form assumed for the power spectrum of primordial density fluctuations. If this is taken to be a scale-free power-law, the five-year WMAP data imply $\Omega_{\rm b}h^2=0.02273\pm0.00062$ or $\eta_{10}=6.23\pm0.17$ [67] as shown in Fig. 22.1. Other assumptions for the shape of the power spectrum can lead to baryon densities as low as $\Omega_{\rm b}h^2=0.0175\pm0.0007$ [68]. Thus, outstanding uncertainties regarding priors are a source of systematic error which presently exceeds the statistical error in the prediction for η .

It is remarkable that the CMB estimate of the baryon density is consistent with the BBN range quoted in Eq. (22.6), and in very good agreement with the value inferred from recent high-redshift D/H measurements [33] and 4 He determinations; together these observations span diverse environments from redshifts z=1000 to the present.

Bearing in mind the importance of priors, the promise of precision determinations of the baryon density using the CMB motivates the use of this value as an input to BBN calculations. Within the context of the Standard Model, BBN then becomes a zero-parameter theory, and the light element abundances are completely determined to within the uncertainties in $\eta_{\rm CMB}$ and the BBN theoretical errors. Comparison with the observed abundances then can be used to test the astrophysics of post-BBN light element evolution [71]. Alternatively, one can consider possible physics beyond the Standard Model (e.g., which might change the expansion rate during BBN) and then use all of the abundances to test such models; this is the subject of our final section.

22.4. The Lithium Problem

As Fig. 22.1 shows, stellar Li/H measurements are inconsistent with the CMB (and D/H), given the error budgets we have quoted. Recent updates in nuclear cross sections, stellar abundance systematics, and the WMAP results all *increase* the discrepancy to as much as 5.3σ , depending on the stellar abundance analysis adopted. [14].

The question then becomes more pressing as to whether this mismatch comes from systematic errors in the observed abundances, and/or uncertainties in stellar astrophysics or nuclear inputs, or whether there might be new physics at work [7]. Nucleosynthesis models in which the baryon-to-photon ratio is inhomogeneous can alter abundances for a given $\eta_{\rm BBN}$, but will overproduce ⁷Li [69]. Entropy generation by some non-standard process could have decreased η between the BBN era and CMB decoupling, however the lack of

spectral distortions in the CMB rules out any significant energy injection upto a redshift $z\sim 10^7$ [70]. The most intriguing resolution of the lithium problem thus involves new physics during BBN [5–6].

For now this is a central unresolved issue in BBN. Nevertheless, the remarkable concordance between the CMB and D/H, as well as 4 He, remain as non-trivial successes, and open windows onto the early Universe and particle physics, as we now discuss.

22.5. Beyond the Standard Model

Given the simple physics underlying BBN, it is remarkable that it still provides the most effective test for the cosmological viability of ideas concerning physics beyond the Standard Model. Although baryogenesis and inflation must have occurred at higher temperatures in the early Universe, we do not as yet have 'standard models' for these, so BBN still marks the boundary between the established and the speculative in Big Bang cosmology. It might appear possible to push the boundary back to the quark-hadron transition at $T \sim \Lambda_{\rm QCD}$, or electroweak symmetry breaking at $T \sim 1/\sqrt{G_{\rm F}}$; however, so far no observable relics of these epochs have been identified, either theoretically or observationally. Thus, although the Standard Model provides a precise description of physics up to the Fermi scale, cosmology cannot be traced in detail before the BBN era.

Limits on particle physics beyond the Standard Model come mainly from the observational bounds on the ⁴He abundance. This is proportional to the n/p ratio which is determined when the weakinteraction rates fall behind the Hubble expansion rate at $T_{\rm fr} \sim 1$ MeV. The presence of additional neutrino flavors (or of any other relativistic species) at this time increases g_* , hence the expansion rate, leading to a larger value of $T_{\rm fr},~n/p,$ and therefore $Y_{\rm p}$ [10,72]. In the Standard Model, the number of relativistic particle species at 1 MeV is $g_* = 5.5 + \frac{7}{4}N_{\nu}$, where the factor 5.5 accounts for photons and e^{\pm} . and N_{ν} is the effective number of (nearly massless) neutrino flavors (see Big Bang Cosmology review). The helium curves in Fig. 22.1 were computed taking $N_{\nu} = 3$; small corrections for non-equilibrium neutrino heating [19] are included in the thermal evolution and lead to an effective $N_{\nu} = 3.04$ compared to assuming instantaneous neutrino freezeout (see, e.g., Big Bang Cosmology review). The computed ⁴He abundance scales as $\Delta Y_{\rm p} \simeq 0.013 \Delta N_{\nu}$ [11]. Clearly the central value for N_{ν} from BBN will depend on η , which is independently determined (with weaker sensitivity to N_{ν}) by the adopted D or ⁷Li abundance. For example, if the best value for the observed primordial ⁴He abundance is 0.249, then, for $\eta_{10} \sim 6$, the central value for N_{ν} is very close to 3. This limit depends sensitively on the adopted light element abundances, particularly $Y_{\rm p}$. A maximum likelihood analysis on η and N_{ν} based on the above ⁴He and D abundances finds the (correlated) 95% CL ranges to be $4.9 < \eta_{10} < 7.1$ and $1.8 < N_{\nu} < 4.5$ [73]. Similar results were obtained in another study [74] which presented a simpler method to extract such bounds based on χ^2 statistics, given a set of input abundances. Using the CMB determination of η improves the constraints: including the most recent WMAP data yields $N_{\nu} < 4.2 \ (95\% \ {\rm CL}) \ [75]$. It is also worth noting that CMB damping tail measurements alone now find $N_{\nu} = 3.85 \pm 0.62$ [45].

Just as one can use the measured helium abundance to place limits on g_* [72], any changes in the strong, weak, electromagnetic, or gravitational coupling constants, arising e.g., from the dynamics of new dimensions, can be similarly constrained [76], as can be any speed-up of the expansion rate in e.g. scalar-tensor theories of gravity [77].

The limits on N_{ν} can be translated into limits on other types of particles or particle masses that would affect the expansion rate of the Universe during nucleosynthesis. For example, consider 'sterile' neutrinos with only right-handed interactions of strength $G_{\rm R} < G_{\rm F}$. Such particles would decouple at higher temperature than (left-handed) neutrinos, so their number density ($\propto T^3$) relative to neutrinos would be reduced by any subsequent entropy release, e.g., due to annihilations of massive particles that become non-relativistic between the two decoupling temperatures. Thus (relativistic) particles with less than full strength weak interactions contribute less to the energy density than particles that remain in equilibrium up to the time of nucleosynthesis [78]. If we impose $N_{\nu} < 4$ as an

illustrative constraint, then the three right-handed neutrinos must have a temperature $3(T_{\nu_{\rm R}}/T_{\nu_{\rm L}})^4 < 1$. Since the temperature of the decoupled ν_R 's is determined by entropy conservation (see Big Bang Cosmology review), $T_{\nu_{\rm R}}/T_{\nu_{\rm L}}=[(43/4)/g_*(T_{\rm d})]^{1/3}<0.76$, where $T_{\rm d}$ is the decoupling temperature of the $\nu_{\rm R}$'s. This requires $g_*(T_{\rm d})>24$, so decoupling must have occurred at $T_{\rm d} > 140$ MeV. The decoupling temperature is related to $G_{\rm R}$ through $(G_{\rm R}/G_{\rm F})^2 \sim (T_{\rm d}/3\,{\rm MeV})^{-3}$, where 3 MeV is the decoupling temperature for $\nu_{\rm L}$ s. This yields a limit $G_{\rm R} \lesssim 10^{-2} G_{\rm F}$. The above argument sets lower limits on the masses of new Z' gauge bosons to which right-handed neutrinos would be coupled in models of superstrings [79], or extended technicolor [80]. Similarly a Dirac magnetic moment for neutrinos, which would allow the right-handed states to be produced through scattering and thus increase q_* , can be significantly constrained [81], as can any new interactions for neutrinos which have a similar effect [82]. Righthanded states can be populated directly by helicity-flip scattering if the neutrino mass is large enough, and this property has been used to infer a bound of $m_{\nu_{\tau}} \lesssim 1$ MeV taking $N_{\nu} < 4$ [83]. If there is mixing between active and sterile neutrinos then the effect on BBN is more complicated [84].

The limit on the expansion rate during BBN can also be translated into bounds on the mass/lifetime of non-relativistic particles which decay during BBN. This results in an even faster speed-up rate, and typically also change the entropy [85]. If the decays include Standard Model particles, the resulting electromagnetic [86–87] and/or hadronic [88] cascades can strongly perturb the light elements, which leads to even stronger constraints. Such arguments have been applied to rule out a MeV mass ν_{τ} , which decays during nucleosynthesis [89].

Such arguments have proved very effective in constraining supersymmetry. For example, if the gravitino is very light and contributes to g_* , the illustrative BBN limit $N_{\nu} < 4$ requires its mass to exceed ~ 1 eV [90]. Alternatively, much recent interest has focussed on the case in which the next-to-lightest supersymmetric particle is metastable and decays during or after BBN. The constraints on unstable particles discussed above imply stringent bounds on the allowed abundance of such particles [88]; if the metastable particle is charged (e.g., the stau), then it is possible for it to form atom-like electromagnetic bound states with nuclei, and the resulting impact on light elements can be quite complex [91]. Such decays can destroy ⁷Li and/or produce ⁶Li, leading to a possible supersymmetric solution to the lithium problems noted above [92](see [5] for a review). In addition, these arguments impose powerful constraints on supersymmetric inflationary cosmology [87-88], in particular thermal leptogenesis [93]. These can be evaded only if the gravitino is massive enough to decay before BBN, i.e., $m_{3/2} \gtrsim 50 \text{ TeV } [94]($ which would be unnatural), or if it is in fact the lightest supersymmetric particle and thus stable [87,95]. Similar constraints apply to moduli – very weakly coupled fields in string theory which obtain an electroweak-scale mass from supersymmetry breaking [96].

Finally, we mention that BBN places powerful constraints on the possibility that there are new large dimensions in nature, perhaps enabling the scale of quantum gravity to be as low as the electroweak scale [97]. Thus, Standard Model fields may be localized on a 'brane,' while gravity alone propagates in the 'bulk.' It has been further noted that the new dimensions may be non-compact, even infinite [98], and the cosmology of such models has attracted considerable attention. The expansion rate in the early Universe can be significantly modified, so BBN is able to set interesting constraints on such possibilities [99].

23. THE COSMOLOGICAL PARAMETERS

Updated September 2011, by O. Lahav (University College London) and A.R. Liddle (University of Sussex).

23.1. Parametrizing the Universe

Rapid advances in observational cosmology have led to the establishment of a precision cosmological model, with many of the key cosmological parameters determined to one or two significant figure accuracy. Particularly prominent are measurements of cosmic microwave background (CMB) anisotropies, led by the seven-year results from the Wilkinson Microwave Anisotropy Probe (WMAP) [1–3]. However the most accurate model of the Universe requires consideration of a wide range of different types of observation, with complementary probes providing consistency checks, lifting parameter degeneracies, and enabling the strongest constraints to be placed.

The term 'cosmological parameters' is forever increasing in its scope, and nowadays includes the parametrization of some functions, as well as simple numbers describing properties of the Universe. The original usage referred to the parameters describing the global dynamics of the Universe, such as its expansion rate and curvature. Also now of great interest is how the matter budget of the Universe is built up from its constituents: baryons, photons, neutrinos, dark matter, and dark energy. We need to describe the nature of perturbations in the Universe, through global statistical descriptors such as the matter and radiation power spectra. There may also be parameters describing the physical state of the Universe, such as the ionization fraction as a function of time during the era since recombination. Typical comparisons of cosmological models with observational data now feature between five and ten parameters.

23.1.1. The global description of the Universe:

Ordinarily, the Universe is taken to be a perturbed Robertson–Walker space-time with dynamics governed by Einstein's equations. This is described in detail by Olive and Peacock in this volume. Using the density parameters Ω_i for the various matter species and Ω_{Λ} for the cosmological constant, the Friedmann equation can be written

$$\sum_{i} \Omega_i + \Omega_{\Lambda} - 1 = \frac{k}{R^2 H^2}, \qquad (23.1)$$

where the sum is over all the different species of material in the Universe. This equation applies at any epoch, but later in this article we will use the symbols Ω_i and Ω_{Λ} to refer to the present values. A typical collection would be baryons, photons, neutrinos, and dark matter (given charge neutrality, the electron density is guaranteed to be too small to be worth considering separately and is included with the baryons).

The complete present state of the homogeneous Universe can be described by giving the current values of all the density parameters and of the Hubble parameter h. These also allow us to track the history of the Universe back in time, at least until an epoch where interactions allow interchanges between the densities of the different species, which is believed to have last happened at neutrino decoupling, shortly before Big Bang Nucleosynthesis (BBN). To probe further back into the Universe's history requires assumptions about particle interactions, and perhaps about the nature of physical laws themselves.

23.1.2. *Neutrinos* :

The standard neutrino sector has three flavors. For neutrinos of mass in the range $5\times 10^{-4}\,\mathrm{eV}$ to 1 MeV, the density parameter in neutrinos is predicted to be

$$\Omega_{\nu}h^2 = \frac{\sum m_{\nu}}{93 \,\text{eV}},\tag{23.2}$$

where the sum is over all families with mass in that range (higher masses need a more sophisticated calculation). We use units with c=1 throughout. Results on atmospheric and Solar neutrino oscillations [4] imply non-zero mass-squared differences between the three neutrino flavors. These oscillation experiments cannot tell us the absolute neutrino masses, but within the simple assumption of a mass hierarchy suggest a lower limit of approximately 0.05 eV on the sum of the neutrino masses.

For a total mass as small as $0.1\,\mathrm{eV}$, this could have a potentially observable effect on the formation of structure, as neutrino free-streaming damps the growth of perturbations. Present cosmological observations have shown no convincing evidence of any effects from either neutrino masses or an otherwise non-standard neutrino sector, and impose quite stringent limits, which we summarize in Section 23.3.4. Accordingly, the usual assumption is that the masses are too small to have a significant cosmological impact at present data accuracy. However, we note that the inclusion of neutrino mass as a free parameter can affect the derived values of other cosmological parameters.

The cosmological effect of neutrinos can also be modified if the neutrinos have decay channels, or if there is a large asymmetry in the lepton sector manifested as a different number density of neutrinos versus anti-neutrinos. This latter effect would need to be of order unity to be significant (rather than the 10^{-9} seen in the baryon sector), which may be in conflict with nucleosynthesis [5].

23.1.3. Inflation and perturbations:

A complete model of the Universe should include a description of deviations from homogeneity, at least in a statistical way. Indeed, some of the most powerful probes of the parameters described above come from the evolution of perturbations, so their study is naturally intertwined in the determination of cosmological parameters.

There are many different notations used to describe the perturbations, both in terms of the quantity used to describe the perturbations and the definition of the statistical measure. We use the dimensionless power spectrum Δ^2 as defined in Olive and Peacock (also denoted $\mathcal P$ in some of the literature). If the perturbations obey Gaussian statistics, the power spectrum provides a complete description of their properties.

From a theoretical perspective, a useful quantity to describe the perturbations is the curvature perturbation \mathcal{R} , which measures the spatial curvature of a comoving slicing of the space-time. A case of particular interest is the Harrison–Zel'dovich spectrum, which corresponds to a constant $\Delta^2_{\mathcal{R}}$. More generally, one can approximate the spectrum by a power-law, writing

$$\Delta_{\mathcal{R}}^2(k) = \Delta_{\mathcal{R}}^2(k_*) \left[\frac{k}{k_*} \right]^{n-1} , \qquad (23.3)$$

where n is known as the spectral index, always defined so that n=1 for the Harrison–Zel'dovich spectrum, and k_* is an arbitrarily chosen scale. The initial spectrum, defined at some early epoch of the Universe's history, is usually taken to have a simple form such as this power-law, and we will see that observations require n close to one, which corresponds to the perturbations in the curvature being independent of scale. Subsequent evolution will modify the spectrum from its initial form.

The simplest viable mechanism for generating the observed perturbations is the inflationary cosmology, which posits a period of accelerated expansion in the Universe's early stages [6,7]. It is a useful working hypothesis that this is the sole mechanism for generating perturbations, and it may further be assumed to be the simplest class of inflationary model, where the dynamics are equivalent to that of a single scalar field ϕ slowly rolling on a potential $V(\phi)$. One may seek to verify that this simple picture can match observations and to determine the properties of $V(\phi)$ from the observational data. Alternatively, more complicated models, perhaps motivated by contemporary fundamental physics ideas, may be tested on a model-by-model basis.

Inflation generates perturbations through the amplification of quantum fluctuations, which are stretched to astrophysical scales by the rapid expansion. The simplest models generate two types, density perturbations which come from fluctuations in the scalar field and its corresponding scalar metric perturbation, and gravitational waves which are tensor metric fluctuations. The former experience gravitational instability and lead to structure formation, while the latter can influence the CMB anisotropies. Defining slow-roll parameters, with primes indicating derivatives with respect to the scalar field, as

$$\epsilon = \frac{m_{\rm Pl}^2}{16\pi} \left(\frac{V'}{V}\right)^2 \quad ; \quad \eta = \frac{m_{\rm Pl}^2 V''}{8\pi V},$$
(23.4)

which should satisfy ϵ , $|\eta| \ll 1$, the spectra can be computed using the slow-roll approximation as

$$\Delta_{\mathcal{R}}^2(k) \simeq \frac{8}{3m_{\text{Pl}}^4} \frac{V}{\epsilon} \bigg|_{k=aH} \quad ; \quad \Delta_{\text{grav}}^2(k) \simeq \frac{128}{3m_{\text{Pl}}^4} V \bigg|_{k=aH} \quad . \quad (23.5)$$

In each case, the expressions on the right-hand side are to be evaluated when the scale k is equal to the Hubble radius during inflation. The symbol ' \simeq ' here indicates use of the slow-roll approximation, which is expected to be accurate to a few percent or better.

From these expressions, we can compute the spectral indices

$$n \simeq 1 - 6\epsilon + 2\eta$$
 ; $n_{\text{grav}} \simeq -2\epsilon$. (23.6)

Another useful quantity is the ratio of the two spectra, defined by

$$r \equiv \frac{\Delta_{\text{grav}}^2(k_*)}{\Delta_{\mathcal{D}}^2(k_*)} \,. \tag{23.7}$$

This convention matches that used by WMAP [2] (there are some alternative historical definitions which lead to a slightly different prefactor in the following equation). We have

$$r \simeq 16\epsilon \simeq -8n_{\rm grav}$$
, (23.8)

which is known as the consistency equation.

In general, one could consider corrections to the power-law approximation, which we discuss later. However, for now we make the working assumption that the spectra can be approximated by power laws. The consistency equation shows that r and $n_{\rm grav}$ are not independent parameters, and so the simplest inflation models give initial conditions described by three parameters, usually taken as $\Delta^2_{\mathcal{R}}$, n, and r, all to be evaluated at some scale k_* , usually the 'statistical center' of the range explored by the data. Alternatively, one could use the parametrization V, ϵ , and η , all evaluated at a point on the putative inflationary potential.

After the perturbations are created in the early Universe, they undergo a complex evolution up until the time they are observed in the present Universe. While the perturbations are small, this can be accurately followed using a linear theory numerical code such as CMBFAST or CAMB [8]. This works right up to the present for the CMB, but for density perturbations on small scales non-linear evolution is important and can be addressed by a variety of semi-analytical and numerical techniques. However the analysis is made, the outcome of the evolution is in principle determined by the cosmological model, and by the parameters describing the initial perturbations, and hence can be used to determine them.

Of particular interest are CMB anisotropies. Both the total intensity and two independent polarization modes are predicted to have anisotropies. These can be described by the radiation angular power spectra C_ℓ as defined in the article of Scott and Smoot in this volume, and again provide a complete description if the density perturbations are Gaussian.

${\bf 23.1.4.} \quad The \ standard \ cosmological \ model:$

We now have most of the ingredients in place to describe the cosmological model. Beyond those of the previous subsections, there are two parameters which are essential: a measure of the ionization state of the Universe and the galaxy bias parameter. The Universe is known to be highly ionized at low redshifts (otherwise radiation from distant quasars would be heavily absorbed in the ultra-violet), and the ionized electrons can scatter microwave photons altering the pattern of observed anisotropies. The most convenient parameter to describe this is the optical depth to scattering τ (i.e., the probability that a given photon scatters once); in the approximation of instantaneous and complete reionization, this could equivalently be described by the redshift of reionization z_{ion} . The bias parameter, described fully later, is needed to relate the observed galaxy power spectrum to the predicted dark matter power spectrum. The basic set of cosmological parameters is therefore as shown in Table 23.1. The spatial curvature does not appear in the list, because it can be determined from the other parameters using Eq. (23.1) (and is assumed zero for the observed

values shown). The total present matter density $\Omega_{\rm m} = \Omega_{\rm cdm} + \Omega_{\rm b}$ is sometimes used in place of the dark matter density.

Most attention to date has been on parameter estimation, where a set of parameters is chosen by hand and the aim is to constrain them. Interest has been growing towards the higher-level inference problem of model selection, which compares different choices of parameter sets. Bayesian inference offers an attractive framework for cosmological model selection, setting a tension between model predictiveness and ability to fit the data.

Table 23.1: The basic set of cosmological parameters. We give values (with some additional rounding) as obtained using a fit of a spatially-flat Λ CDM cosmology with a power-law initial spectrum to WMAP7 data alone: Table 10, left column of Ref. 2. Tensors are assumed zero except in quoting a limit on them. The exact values and uncertainties depend on both the precise data-sets used and the choice of parameters allowed to vary. Limits on Ω_{Λ} and h weaken if the Universe is not assumed flat. The density perturbation amplitude is specified by the derived parameter σ_8 . Uncertainties are one-sigma/68% confidence unless otherwise stated.

| Parameter | Symbol | Value |
|-----------------------------------------------------------|--------------------------|-------------------------------------------|
| Hubble parameter | h | 0.704 ± 0.025 |
| Cold dark matter density | $\Omega_{ m cdm}$ | $\Omega_{\rm cdm} h^2 = 0.112 \pm 0.006$ |
| Baryon density | $\Omega_{ m b}$ | $\Omega_{\rm b}h^2 = 0.0225 \pm 0.0006$ |
| Cosmological constant | Ω_{Λ} | 0.73 ± 0.03 |
| Radiation density | $\Omega_{ m r}$ | $\Omega_{\rm r}h^2 = 2.47 \times 10^{-5}$ |
| Neutrino density | $\Omega_{ u}$ | See Sec. 23.1.2 |
| Density perturb. amplitude at $k = 0.002 \text{Mpc}^{-1}$ | $\Delta_{\mathcal{R}}^2$ | $(2.43 \pm 0.11) \times 10^{-9}$ |
| Density perturb. spectral index | n | 0.967 ± 0.014 |
| Tensor to scalar ratio | r | $r < 0.36 \ (95\% \ \text{conf.})$ |
| Ionization optical depth | au | 0.088 ± 0.015 |
| Bias parameter | b | See Sec. 23.3.4 |

As described in Sec. 23.4, models based on these eleven parameters are able to give a good fit to the complete set of high-quality data available at present, and indeed some simplification is possible. Observations are consistent with spatial flatness, and indeed the inflation models so far described automatically generate negligible spatial curvature, so we can set k = 0; the density parameters then must sum to unity, and so one can be eliminated. The neutrino energy density is often not taken as an independent parameter. Provided the neutrino sector has the standard interactions, the neutrino energy density, while relativistic, can be related to the photon density using thermal physics arguments, and it is currently difficult to see the effect of the neutrino mass, although observations of large-scale structure have already placed interesting upper limits. This reduces the standard parameter set to nine. In addition, there is no observational evidence for the existence of tensor perturbations (though the upper limits are fairly weak), and so r could be set to zero. Presently n is in a somewhat uncertain position regarding whether it needs to be varied in a fit, or can be set to the Harrison-Zel'dovich value n=1. Parameter estimation [3] indicates n=1 is disfavoured at over $2-\sigma$, but Bayesian model selection techniques [9] suggest the data is not conclusive. With n set to one, this leaves seven parameters, which is the smallest set that can usefully be compared to the present cosmological data set. This model (usually with n kept as a parameter) is referred to by various names, including ΛCDM , the concordance cosmology, and the standard cosmological model.

Of these parameters, only $\Omega_{\rm r}$ is accurately measured directly. The radiation density is dominated by the energy in the CMB, and the COBE satellite FIRAS experiment determined its temperature to be $T=2.7255\pm0.0006\,{\rm K}$ [10], corresponding to $\Omega_{\rm r}=2.47\times10^{-5}h^{-2}$. It typically need not be varied in fitting other data. If galaxy clustering

data are not included in a fit, then the bias parameter is also unnecessary.

In addition to this minimal set, there is a range of other parameters which might prove important in future as the data-sets further improve, but for which there is so far no direct evidence, allowing them to be set to a specific value for now. We discuss various speculative options in the next section. For completeness at this point, we mention one other interesting parameter, the helium fraction, which is a non-zero parameter that can affect the CMB anisotropies at a subtle level. Presently, BBN provides the best measurement of this parameter (see the Fields and Sarkar article in this volume), and it is usually fixed in microwave anisotropy studies, but the data are just reaching a level where allowing its variation may become mandatory.

23.1.5. Derived parameters:

The parameter list of the previous subsection is sufficient to give a complete description of cosmological models which agree with observational data. However, it is not a unique parametrization, and one could instead use parameters derived from that basic set. Parameters which can be obtained from the set given above include the age of the Universe, the present horizon distance, the present neutrino background temperature, the epoch of matter-radiation equality, the epochs of recombination and decoupling, the epoch of transition to an accelerating Universe, the baryon-to-photon ratio, and the baryon to dark matter density ratio. In addition, the physical densities of the matter components, $\Omega_i h^2$, are often more useful than the density parameters. The density perturbation amplitude can be specified in many different ways other than the large-scale primordial amplitude, for instance, in terms of its effect on the CMB, or by specifying a short-scale quantity, a common choice being the present linear-theory mass dispersion on a scale of $8 h^{-1}$ Mpc, known as σ_8 , whose WMAP7 value is 0.81 ± 0.03 [2].

Different types of observation are sensitive to different subsets of the full cosmological parameter set, and some are more naturally interpreted in terms of some of the derived parameters of this subsection than on the original base parameter set. In particular, most types of observation feature degeneracies whereby they are unable to separate the effects of simultaneously varying several of the base parameters.

23.2. Extensions to the standard model

This section discusses some ways in which the standard model could be extended. At present, there is no positive evidence in favor of any of these possibilities, which are becoming increasingly constrained by the data, though there always remains the possibility of trace effects at a level below present observational capability.

23.2.1. More general perturbations:

The standard cosmology assumes adiabatic, Gaussian perturbations. Adiabaticity means that all types of material in the Universe share a common perturbation, so that if the space-time is foliated by constant-density hypersurfaces, then all fluids and fields are homogeneous on those slices, with the perturbations completely described by the variation of the spatial curvature of the slices. Gaussianity means that the initial perturbations obey Gaussian statistics, with the amplitudes of waves of different wavenumbers being randomly drawn from a Gaussian distribution of width given by the power spectrum. Note that gravitational instability generates non-Gaussianity; in this context, Gaussianity refers to a property of the initial perturbations, before they evolve significantly.

The simplest inflation models, based on one dynamical field, predict adiabatic perturbations and a level of non-Gaussianity which is too small to be detected by any experiment so far conceived. For present data, the primordial spectra are usually assumed to be power laws.

23.2.1.1. Non-power-law spectra:

For typical inflation models, it is an approximation to take the spectra as power laws, albeit usually a good one. As data quality improves, one might expect this approximation to come under pressure, requiring a more accurate description of the initial spectra, particularly for the density perturbations. In general, one can expand $\ln \Delta_{\mathcal{R}}^2$ as

$$\ln \Delta_{\mathcal{R}}^2(k) = \ln \Delta_{\mathcal{R}}^2(k_*) + (n_* - 1) \ln \frac{k}{k_*} + \frac{1}{2} \left. \frac{dn}{d \ln k} \right|_{*} \ln^2 \frac{k}{k_*} + \cdots, (23.9)$$

where the coefficients are all evaluated at some scale k_* . The term $dn/d\ln k|_*$ is often called the running of the spectral index [11]. Once non-power-law spectra are allowed, it is necessary to specify the scale k_* at which the spectral index is defined.

23.2.1.2. *Isocurvature perturbations:*

An isocurvature perturbation is one which leaves the total density unperturbed, while perturbing the relative amounts of different materials. If the Universe contains N fluids, there is one growing adiabatic mode and N-1 growing isocurvature modes (for reviews see Ref. 12 and Ref. 7). These can be excited, for example, in inflationary models where there are two or more fields which acquire dynamically-important perturbations. If one field decays to form normal matter, while the second survives to become the dark matter, this will generate a cold dark matter isocurvature perturbation.

In general, there are also correlations between the different modes, and so the full set of perturbations is described by a matrix giving the spectra and their correlations. Constraining such a general construct is challenging, though constraints on individual modes are beginning to become meaningful, with no evidence that any other than the adiabatic mode must be non-zero.

23.2.1.3. Seeded perturbations:

An alternative to laying down perturbations at very early epochs is that they are seeded throughout cosmic history, for instance by topological defects such as cosmic strings. It has long been excluded that these are the sole original of structure, but they could contribute part of the perturbation signal, current limits being approximately ten percent [13]. In particular, cosmic defects formed in a phase transition ending inflation is a plausible scenario for such a contribution.

23.2.1.4. Non-Gaussianity:

Multi-field inflation models can also generate primordial non-Gaussianity (reviewed, e.g., in Ref. 7). The extra fields can either be in the same sector of the underlying theory as the inflaton, or completely separate, an interesting example of the latter being the curvaton model [14]. Current upper limits on non-Gaussianity are becoming stringent, but there remains much scope to push down those limits and perhaps reveal trace non-Gaussianity in the data. If non-Gaussianity is observed, its nature may favor an inflationary origin, or a different one such as topological defects.

23.2.2. Dark matter properties:

Dark matter properties are discussed in the article by Drees and Gerbier in this volume. The simplest assumption concerning the dark matter is that it has no significant interactions with other matter, and that its particles have a negligible velocity as far as structure formation is concerned. Such dark matter is described as 'cold,' and candidates include the lightest supersymmetric particle, the axion, and primordial black holes. As far as astrophysicists are concerned, a complete specification of the relevant cold dark matter properties is given by the density parameter $\Omega_{\rm cdm}$, though those seeking to directly detect it are as interested in its interaction properties.

Cold dark matter is the standard assumption and gives an excellent fit to observations, except possibly on the shortest scales where there remains some controversy concerning the structure of dwarf galaxies and possible substructure in galaxy halos. It has long been excluded for all the dark matter to have a large velocity dispersion, so-called 'hot' dark matter, as it does not permit galaxies to form; for thermal relics the mass must be below about 1 keV to satisfy this

constraint, though relics produced non-thermally, such as the axion, need not obey this limit. However, in future further parameters might need to be introduced to describe dark matter properties relevant to astrophysical observations. Suggestions which have been made include a modest velocity dispersion (warm dark matter) and dark matter self-interactions. There remains the possibility that the dark matter comprises two separate components, e.g., a cold one and a hot one, an example being if massive neutrinos have a non-negligible effect.

23.2.3. Dark energy:

While the standard cosmological model given above features a cosmological constant, in order to explain observations indicating that the Universe is presently accelerating, further possibilities exist under the general heading 'dark energy'. One possibility, usually called quintessence, is that a scalar field is responsible, with the mechanism mimicking that of early Universe inflation [15]. As described by Olive and Peacock, a fairly model-independent description of dark energy can be given using the equation of state parameter w, with w=-1 corresponding to a cosmological constant and w potentially varying with redshift. For high-precision predictions of CMB anisotropies, the scalar-field description has the advantage of a self-consistent evolution of the 'sound speed' associated with the dark energy perturbations.

A competing possibility is that the observed acceleration is due to a modification of gravity, i.e., the left-hand side of Einstein's equation rather than the right (for a review see Ref. 16). Observations of expansion kinematics alone cannot distinguish these two possibilities, but probes of the growth rate of structure formation may be able to. It is possible that certain modified theories of gravity could explain the late-time acceleration of the Universe without recourse to any dark energy or cosmological constant. In a 'Newtonian' gauge the perturbed metric can be written with two potentials. Non-relativistic particles only respond to the temporal one, essentially the Newtonian potential, while relativistic particles, e.g., photons, respond to the full metric in the form of the sum of the two potentials. In standard general relativity the two potentials are the same (in absence of anisotropic stress). Measurements of redshift distortions from spectroscopic surveys and weak lensing from imaging surveys can in principle distinguish between the Dark Energy and Modified Gravity alternatives (e.g., Ref. 17).

While present observations are consistent with a cosmological constant, to test dark energy models w must be varied. The most popular option is $w(a) = w_0 + (1-a)w_a$ with w_0 and w_a constants to be determined [18]. Additionally the weak energy condition $w \ge -1$ may be imposed. Future data may require a more sophisticated parametrization of the dark energy, including its sound speed which influences structure formation.

23.2.4. Complex ionization history:

The full ionization history of the Universe is given by the ionization fraction as a function of redshift z. The simplest scenario takes the ionization to have the small residual value left after recombination up to some redshift $z_{\rm ion}$, at which point the Universe instantaneously reionizes completely. Then there is a one-to-one correspondence between τ and $z_{\rm ion}$ (that relation, however, also depending on other cosmological parameters). An accurate treatment of this process will track separate histories for hydrogen and helium. While currently rapid ionization appears to be a good approximation, as data improve a more complex ionization history may need to be considered.

23.2.5. Varying 'constants':

Variation of the fundamental constants of Nature over cosmological times is another possible enhancement of the standard cosmology. There is a long history of study of variation of the gravitational constant G, and more recently attention has been drawn to the possibility of small fractional variations in the fine-structure constant. There is presently no observational evidence for the former, which is tightly constrained by a variety of measurements. Evidence for

the latter has been claimed from studies of spectral line shifts in quasar spectra at redshifts of order two [19], but this is presently controversial and in need of further observational study.

23.2.6. Cosmic topology:

The usual hypothesis is that the Universe has the simplest topology consistent with its geometry, for example that a flat Universe extends forever. Observations cannot tell us whether that is true, but they can test the possibility of a non-trivial topology on scales up to roughly the present Hubble scale. Extra parameters would be needed to specify both the type and scale of the topology, for example, a cuboidal topology would need specification of the three principal axis lengths. At present, there is no direct evidence for cosmic topology, though the low values of the observed cosmic microwave quadrupole and octupole have been cited as a possible signature [20].

23.3. Probes

The goal of the observational cosmologist is to utilize astronomical information to derive cosmological parameters. The transformation from the observables to the key parameters usually involves many assumptions about the nature of the objects, as well as about the nature of the dark matter. Below we outline the physical processes involved in each probe, and the main recent results. The first two subsections concern probes of the homogeneous Universe, while the remainder consider constraints from perturbations.

In addition to statistical uncertainties we note three sources of systematic uncertainties that will apply to the cosmological parameters of interest: (i) due to the assumptions on the cosmological model and its priors (i.e., the number of assumed cosmological parameters and their allowed range); (ii) due to the uncertainty in the astrophysics of the objects (e.g., light curve fitting for supernovae or the mass–temperature relation of galaxy clusters); and (iii) due to instrumental and observational limitations (e.g., the effect of 'seeing' on weak gravitational lensing measurements, or beam shape on CMB anisotropy measurements).

23.3.1. Direct measures of the Hubble constant:

In 1929, Edwin Hubble discovered the law of expansion of the Universe by measuring distances to nearby galaxies. The slope of the relation between the distance and recession velocity is defined to be the Hubble constant H_0 . Astronomers argued for decades on the systematic uncertainties in various methods and derived values over the wide range, $40\,\mathrm{km\,s^{-1}\,Mpc^{-1}} \lesssim H_0 \lesssim 100\,\mathrm{km\,s^{-1}\,Mpc^{-1}}$.

One of the most reliable results on the Hubble constant comes from the Hubble Space Telescope Key Project [21]. This study used the empirical period–luminosity relations for Cepheid variable stars to obtain distances to 31 galaxies, and calibrated a number of secondary distance indicators—Type Ia Supernovae (SNe Ia), the Tully–Fisher relation, surface-brightness fluctuations, and Type II Supernovae—measured over distances of 400 to 600 Mpc. They estimated $H_0=72\pm3$ (statistical) ±7 (systematic) km s $^{-1}$ Mpc $^{-1}$. \ddagger

A recent study [22] of over 600 Cepheids in the host galaxies of eight recent SNe Ia, observed with an improved camera on board the Hubble Space Telescope, was used to calibrate the magnitude–redshift relation for 240 SNe Ia. This yielded an even more accurate figure, $H_0 = 73.8 \pm 2.4 \, \mathrm{km \, s^{-1} \, Mpc^{-1}}$ (including both statistical and systematic errors). The major sources of uncertainty in this result are due to the heavy element abundance of the Cepheids and the distance to the fiducial nearby galaxy, the Large Magellanic Cloud, relative to which all Cepheid distances are measured. It is impressive that this result is in such good agreement with the result derived from the WMAP CMB measurements combined with other probes (see Table 23.2).

[†] It is actually the negative pressure of this material, not its energy, that is responsible for giving the acceleration. Furthermore, while generally in physics matter and energy are interchangeable terms, dark matter and dark energy are quite distinct concepts.

[‡] Unless stated otherwise, all quoted uncertainties in this article are one-sigma/68% confidence. Cosmological parameters often have significantly non-Gaussian uncertainties. Throughout we have rounded central values, and especially uncertainties, from original sources in cases where they appear to be given to excessive precision.

${\bf 23.3.2.} \quad Supernovae \ as \ cosmological \ probes:$

The relation between observed flux and the intrinsic luminosity of an object depends on the luminosity distance $D_{\rm L}$, which in turn depends on cosmological parameters:

$$D_{\rm L} = (1+z)r_e(z)\,, (23.10)$$

where $r_e(z)$ is the coordinate distance. For example, in a flat Universe

$$r_e(z) = \int_0^z \frac{dz'}{H(z')}$$
 (23.11)

For a general dark energy equation of state $w(z) = p_{\rm de}(z)/\rho_{\rm de}(z)$, the Hubble parameter is, still considering only the flat case,

$$\frac{H^2(z)}{H_0^2} = (1+z)^3 \Omega_{\rm m} + \Omega_{\rm de} \exp[3X(z)], \qquad (23.12)$$

where

$$X(z) = \int_0^z [1 + w(z')](1 + z')^{-1} dz', \qquad (23.13)$$

and Ω_{de} is the present density parameter of the dark energy component. If a general equation of state is allowed, then one has to solve for w(z) (parametrized, for example, as $w(z) = w = \mathrm{const.}$, or $w(z) = w_0 + w_1 z$) as well as for Ω_{de} .

Empirically, the peak luminosity of SNe Ia can be used as an efficient distance indicator (e.g., Ref. 23). The favorite theoretical explanation for SNe Ia is the thermonuclear disruption of carbon–oxygen white dwarfs. Although not perfect 'standard candles,' it has been demonstrated that by correcting for a relation between the light curve shape, color, and the luminosity at maximum brightness, the dispersion of the measured luminosities can be greatly reduced. There are several possible systematic effects which may affect the accuracy of the use of SNe Ia as distance indicators, e.g., evolution with redshift and interstellar extinction in the host galaxy and in the Milky Way.

Two major studies, the Supernova Cosmology Project and the High-z Supernova Search Team, found evidence for an accelerating Universe [24], interpreted as due to a cosmological constant or a dark energy component. Representative results from the 'Union sample' [25] of over 300 SNe Ia are shown in Fig. 23.1 (see also further results in Ref. 26). When combined with the CMB data (which indicates flatness, i.e., $\Omega_{\rm m} + \Omega_{\Lambda} \approx 1$), the best-fit values are $\Omega_{\rm m} \approx 0.3$ and $\Omega_{\Lambda} \approx 0.7$. Most results in the literature are consistent with the w=-1 cosmological constant case. As an example of recent results, the SNLS3 team found, for a constant equation of state parameter, $w=-0.91^{+0.16}_{-0.20} ({\rm stat.})^{+0.07}_{-0.14} ({\rm sys.})$ [27]. This includes a correction for the recently-discovered relationship between host galaxy mass and supernova absolute brightness. This agrees with earlier results [25,28]. Future experiments will aim to set constraints on the cosmic equation of state w(z), though given the integral relation between the luminosity distance and w(z) it is not straightforward to recover w(z) (e.g., Ref. 29).

${\bf 23.3.3.} \quad Cosmic\ microwave\ background:$

The physics of the CMB is described in detail by Scott and Smoot in this volume. Before recombination, the baryons and photons are tightly coupled, and the perturbations oscillate in the potential wells generated primarily by the dark matter perturbations. After decoupling, the baryons are free to collapse into those potential wells. The CMB carries a record of conditions at the time of last scattering, often called primary anisotropies. In addition, it is affected by various processes as it propagates towards us, including the effect of a time-varying gravitational potential (the integrated Sachs-Wolfe effect), gravitational lensing, and scattering from ionized gas at low redshift.

The primary anisotropies, the integrated Sachs-Wolfe effect, and scattering from a homogeneous distribution of ionized gas, can all be calculated using linear perturbation theory. Available codes include CMBFAST and CAMB [8], the latter widely used embedded within the analysis package CosmoMC [30]. Gravitational lensing is also calculated in these codes. Secondary effects such as inhomogeneities in the reionization process, and scattering from gravitationally-collapsed gas (the Sunyaev–Zel'dovich effect), require more complicated, and more uncertain, calculations.

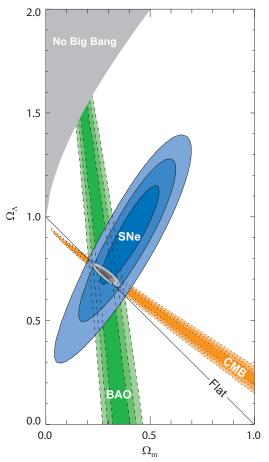

Figure 23.1: Confidence level contours of 68.3%, 95.4% and 99.7% in the Ω_{Λ} - $\Omega_{\rm m}$ plane from the CMB, BAOs and the Union SNe Ia set, as well as their combination (assuming w=-1). [Courtesy of Kowalski *et al.* [25]]

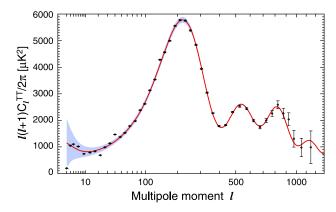

Figure 23.2: The angular power spectrum of the CMB temperature anisotropies from WMAP7, from Ref. 2. The grey band indicates the cosmic variance uncertainty. The solid line shows the prediction from the best-fitting Λ CDM model. [Figure courtesy NASA/WMAP Science Team.]

The upshot is that the detailed pattern of anisotropies depends on all of the cosmological parameters. In a typical cosmology, the anisotropy power spectrum [usually plotted as $\ell(\ell+1)C_\ell$] features a flat plateau at large angular scales (small ℓ), followed by a series of oscillatory features at higher angular scales, the first and most prominent being at around one degree ($\ell \simeq 200$). These features, known as acoustic peaks, represent the oscillations of the photon-baryon fluid around the time of decoupling. Some features can be

closely related to specific parameters—for instance, the location of the first peak probes the spatial geometry, while the relative heights of the peaks probes the baryon density—but many other parameters combine to determine the overall shape.

The seven-year data release from the WMAP satellite [1], henceforth WMAP7, has provided the most powerful results to date on the spectrum of CMB anisotropies, with a precision determination of the temperature power spectrum up to $\ell \simeq 900$, shown in Fig. 23.2, as well as measurements of the spectrum of E-polarization anisotropies and the correlation spectrum between temperature and polarization (those spectra having first been detected by DASI [31]) . These are consistent with models based on the parameters we have described, and provide accurate determinations of many of those parameters [2].

WMAP7 provides an exquisite measurement of the location of the first acoustic peak, determining the angular-diameter distance of the last-scattering surface. In combination with other data this strongly constrains the spatial geometry, in a manner consistent with spatial flatness and excluding significantly-curved Universes. WMAP7 also gives a precision measurement of the age of the Universe. It gives a baryon density consistent with, and at higher precision than, that coming from BBN. It affirms the need for both dark matter and dark energy. It shows no evidence for dynamics of the dark energy, being consistent with a pure cosmological constant (w = -1). The density perturbations are consistent with a power-law primordial spectrum, with indications that the spectral slope may be less than the Harrison–Zel'dovich value n=1 [2]. There is no indication of tensor perturbations, but the upper limit is quite weak. WMAP7's current best-fit for the reionization optical depth, $\tau = 0.088$, is in reasonable agreement with models of how early structure formation induces reionization.

WMAP7 is consistent with other experiments and its dynamic range can be enhanced by including information from small-angle CMB experiments such as ACBAR, QUaD, the South Pole Telescope (SPT), and the Atacama Cosmology Telescope (ACT), which gives extra constraining power on some parameters. ACT has also announced the first detection of gravitational lensing of the CMB from the four-point correlation of temperature variations [32], agreeing with the expected effect in the standard cosmology.

23.3.4. Galaxy clustering:

The power spectrum of density perturbations depends on the nature of the dark matter. Within the Λ CDM model, the power spectrum shape depends primarily on the primordial power spectrum and on the combination $\Omega_{\rm m}h$ which determines the horizon scale at matter–radiation equality, with a subdominant dependence on the baryon density.

The matter distribution is most easily probed by observing the galaxy distribution, but this must be done with care as the galaxies do not perfectly trace the dark matter distribution. Rather, they are a 'biased' tracer of the dark matter. The need to allow for such bias is emphasized by the observation that different types of galaxies show bias with respect to each other. In particular scale-dependent and stochastic biasing may introduce a systematic effect on the determination of cosmological parameters from redshift surveys. Prior knowledge from simulations of galaxy formation or from gravitational lensing data could help to quantify biasing. Furthermore, the observed 3D galaxy distribution is in redshift space, i.e., the observed redshift is the sum of the Hubble expansion and the line-of-sight peculiar velocity, leading to linear and non-linear dynamical effects which also depend on the cosmological parameters. On the largest length scales, the galaxies are expected to trace the location of the dark matter, except for a constant multiplier b to the power spectrum, known as the linear bias parameter. On scales smaller than 20 h^{-1} Mpc or so, the clustering pattern is 'squashed' in the radial direction due to coherent infall, which depends approximately on the parameter $\beta \equiv \Omega_{\rm m}^{0.6}/b$ (on these shorter scales, more complicated forms of biasing are not excluded by the data). On scales of a few h^{-1} Mpc, there is an effect of elongation along the line of sight (colloquially known as the 'finger of God' effect) which depends on the galaxy velocity dispersion.

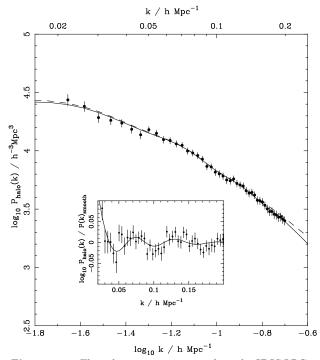

Figure 23.3: The galaxy power spectrum from the SDSS LRGs. The best-fit LRG+WMAP Λ CDM model is shown for two sets of nuisance parameters (solid and dashed lines). The BAO inset shows the same data and model divided by a spline fit to the smooth component. [Figure courtesy B. Reid/W. Percival; see Ref. 35.]

23.3.4.1. Baryonic Acoustic Oscillations (BAOs):

The Fourier power spectra of the 2-degree Field (2dF) Galaxy Redshift Survey and the Sloan Digital Sky Survey (SDSS) are well fitted by a $\Lambda \rm{CDM}$ model and both surveys show evidence for BAOs [33,34]. Further analyses used the Luminous Red Galaxies (LRGs) in the SDSS 7th Data Release [35], shown in Fig. 23.3. Combining the so-called 'halo' power spectrum measurement with the then-current WMAP5 results, for the flat $\Lambda \rm{CDM}$ model they find $\Omega_{\rm m}=0.289\pm0.019$ and $H_0=69.4\pm1.6$ km s $^{-1}$ Mpc $^{-1}$. A new survey, WiggleZ, combined with the 6dF and SDSS-LRG surveys, CMB and SNIa data, yields a constant equation of state $w=-1.03\pm0.08$ for a flat universe, consistent with a cosmological constant. However, allowing for epoch-dependent $w(a)=w_0+(1-a)w_a$ they find that the uncertainties are much larger, $w_0=-1.09\pm0.17$ and $w_a=0.19\pm0.69$ [36]. Further BAO results are expected from the BOSS survey.

23.3.4.2. Integrated Sachs-Wolfe effect:

The integrated Sachs–Wolfe (ISW) effect, described in the article by Scott and Smoot, is the change in CMB photon energy when propagating through the changing gravitational potential wells of developing cosmic structures. In linear theory, the ISW signal is expected in universes where there is dark energy, curvature or modified gravity. Correlating the large-angle CMB anisotropies with very large scale structures, first proposed in Ref. 37, has provided results which vary from no detection of this effect to 4σ detection [38,39].

23.3.4.3. Limits on neutrino mass from galaxy surveys and other probes:

Large-scale structure data can put an upper limit on Ω_{ν} due to the neutrino 'free streaming' effect [40–43]. Upper limits on neutrino mass are commonly estimated by comparing the observed galaxy power spectrum with a four-component model of baryons, cold dark matter, a cosmological constant, and massive neutrinos. Such analyses also assume that the primordial power spectrum is adiabatic, scale-invariant, and Gaussian. Potential systematic effects include biasing of the galaxy distribution and non-linearities of the

power spectrum. An upper limit can also be derived from CMB anisotropies alone, but it is typically not below 2 eV [44]. Additional cosmological data sets can improve the results. Recent results using a photometric redshift sample of LRGs combined with WMAP, BAO, Hubble constant and SNe Ia data brought the upper limit on the total neutrino mass down to 0.28 eV [45], with a similar result for a combination of other data sets [46]. As the lower limit on neutrino mass from terrestrial experiments is 0.05 eV, it looks promising that cosmological surveys will detect the neutrino mass. Another probe of neutrino mass is the intergalactic medium, which manifests itself in quasar absorption lines (the Lyman- α forest), yielding from the SDSS flux power spectrum an upper limit of 0.9 eV (95% confidence) [47].

23.3.5. Clusters of galaxies:

A cluster of galaxies is a large collection of galaxies held together by their mutual gravitational attraction. The largest ones are around 10^{15} Solar masses, and are the largest gravitationally-collapsed structures in the Universe. Even at the present epoch they are relatively rare, with only a few percent of galaxies being in clusters. They provide various ways to study the cosmological parameters.

The first objects of a given kind form at the rare high peaks of the density distribution, and if the primordial density perturbations are Gaussian distributed, their number density is exponentially sensitive to the size of the perturbations, and hence can strongly constrain it. Clusters are an ideal application in the present Universe. They are usually used to constrain the amplitude σ_8 , as a box of side $8 h^{-1}$ Mpc contains about the right amount of material to form a cluster. The most useful observations at present are of X-ray emission from hot gas lying within the cluster, whose temperature is typically a few keV, and which can be used to estimate the mass of the cluster. A theoretical prediction for the mass function of clusters can come either from semi-analytic arguments or from numerical simulations. The same approach can be adopted at high redshift (which for clusters means redshifts of order one) to attempt to measure σ_8 at an earlier epoch. The evolution of σ_8 is primarily driven by the value of the matter density $\Omega_{\rm m}$, with a sub-dominant dependence on the dark energy properties.

At present, the main uncertainty is the relation between the observed gas temperature and the cluster mass, despite extensive study using simulations. Mantz et al. [48] used a large sample of X-ray selected clusters to find $\sigma_8=0.82\pm0.05,\,\Omega_{\rm m}=0.23\pm0.04,$ and $w=-1.01\pm0.20$ for a constant dark energy equation of state w. This agrees well with the values predicted in cosmologies compatible with WMAP7.

A further use of clusters is to measure the ratio of baryon to dark matter mass, through modelling of the way the hot cluster gas is confined by the total gravitational potential. Allen *et al.* [49] give examples of constraints that can be obtained this way on both dark matter and dark energy using Chandra data across a range of redshifts.

23.3.6. Clustering in the inter-galactic medium:

It is commonly assumed, based on hydrodynamic simulations, that the neutral hydrogen in the inter-galactic medium (IGM) can be related to the underlying mass distribution. It is then possible to estimate the matter power spectrum on scales of a few megaparsecs from the absorption observed in quasar spectra, the so-called Lyman- α forest. The usual procedure is to measure the power spectrum of the transmitted flux, and then to infer the mass power spectrum. Photo-ionization heating by the ultraviolet background radiation and adiabatic cooling by the expansion of the Universe combine to give a simple power-law relation between the gas temperature and the baryon density. It also follows that there is a power-law relation between the optical depth τ and $\rho_{\rm b}$. Therefore, the observed flux $F=\exp(-\tau)$ is strongly correlated with $\rho_{\rm b}$, which itself traces the mass density. The matter and flux power spectra can be related by

$$P_{\rm m}(k) = b^2(k) P_F(k),$$
 (23.14)

where b(k) is a bias function which is calibrated from simulations. Croft *et al.* [50] derived cosmological parameters from Keck Telescope observations of the Lyman- α forest at redshifts z=2 to 4. Their derived power spectrum corresponds to that of a CDM model, which is in good agreement with the 2dF galaxy power spectrum. A recent study using VLT spectra [51] agrees with the flux power spectrum of Ref. 50. This method depends on various assumptions. Seljak et al. [52] pointed out that uncertainties are sensitive to the range of cosmological parameters explored in the simulations, and the treatment of the mean transmitted flux. Nevertheless, this method has the potential of measuring accurately the power spectrum of mass perturbations in a different way to other methods.

23.3.7. Gravitational lensing:

Images of background galaxies are distorted by the gravitational effect of mass variations along the line of sight. Deep gravitational potential wells such as galaxy clusters generate 'strong lensing', leading to arcs, arclets and multiple images, while more moderate perturbations give rise to 'weak lensing'. Weak lensing is now widely used to measure the mass power spectrum in selected regions of the sky (see Ref. 53 for recent reviews). As the signal is weak, the image of deformed galaxy shapes (the 'shear map') must be analyzed statistically to measure the power spectrum, higher moments, and cosmological parameters.

The shear measurements are mainly sensitive to the combination of $\Omega_{\rm m}$ and the amplitude σ_8 . For example, the weak lensing signal detected by the CFHT Legacy Survey has been analyzed to yield $\sigma_8(\Omega_{\rm m}/0.25)^{0.64}=0.78\pm0.04$ [54] and $\sigma_8(\Omega_{\rm m}/0.24)^{0.59}=0.84\pm0.05$ [55] assuming a $\Lambda{\rm CDM}$ model. Earlier results are summarized in Ref. 53. There are various systematic effects in the interpretation of weak lensing, e.g., due to atmospheric distortions during observations, the redshift distribution of the background galaxies, the intrinsic correlation of galaxy shapes, and non-linear modeling uncertainties.

23.3.8. Peculiar velocities:

Deviations from the Hubble flow directly probe the mass perturbations in the Universe, and hence provide a powerful probe of the dark matter [56]. Peculiar velocities are deduced from the difference between the redshift and the distance of a galaxy. The observational difficulty is in accurately measuring distances to galaxies. Even the best distance indicators (e.g., the Tully–Fisher relation) give an uncertainty of 15% per galaxy, hence limiting the application of the method at large distances. Peculiar velocities are mainly sensitive to $\Omega_{\rm m}$, not to Ω_{Λ} or dark energy. While at present cosmological parameters derived from peculiar velocities are strongly affected by random and systematic errors, a new generation of surveys may improve their accuracy. Three promising approaches are the 6dF near-infrared survey of 15,000 peculiar velocities, peculiar velocities of SNe Ia, and the kinematic Sunyaev–Zel'dovich effect.

There is also a renewed interest in 'redshift distortion'. As the measured redshift of a galaxy is the sum of its redshift due to the Hubble expansion and its peculiar velocity, this distortion depends on cosmological parameters [57] via the perturbation growth rate $f(z) = d \ln \delta/d \ln a \approx \Omega^{\gamma}(z)$, where $\gamma = 0.55$ for a concordance ΛCDM model, and is different for a modified gravity model. Recent observational results [58,59] show that by measuring f(z) with redshift it is feasible to constrain γ and rule out certain modified gravity models.

23.4. Bringing observations together

Although it contains two ingredients—dark matter and dark energy—which have not yet been verified by laboratory experiments, the $\Lambda \mathrm{CDM}$ model is almost universally accepted by cosmologists as the best description of the present data. The basic ingredients are given by the parameters listed in Sec. 23.1.4, with approximate values of some of the key parameters being $\Omega_\mathrm{b} \approx 0.05$, $\Omega_\mathrm{cdm} \approx 0.23$, $\Omega_\Lambda \approx 0.72$, and a Hubble constant $h \approx 0.70$. The spatial geometry is very close to flat (and usually assumed to be precisely flat), and the initial perturbations Gaussian, adiabatic, and nearly scale-invariant.

The most powerful single experiment is WMAP7, which on its own supports all these main tenets. Values for some parameters, as given in Larson *et al.* [2] and Komatsu *et al.* [3], are reproduced in Table 23.2. These particular results presume a flat Universe. The

constraints are somewhat strengthened by adding additional data-sets, as shown in the Table, though most of the constraining power resides in the WMAP7 data.

Table 23.2: Parameter constraints reproduced from Larson et al. [2] and Komatsu et al. [3], with some additional rounding. All columns assume the ΛCDM cosmology with a power-law initial spectrum, no tensors, spatial flatness, and a cosmological constant as dark energy. Above the line are the six parameter combinations actually fit to the data; those below the line are derived from these. Two different data combinations are shown to highlight the extent to which this choice matters. The first column is WMAP7 alone, while the second column shows a combination of WMAP7 with BAO and H_0 data as described in Ref. 3. The perturbation amplitude $\Delta_{\mathcal{R}}^2$ is specified at the scale $0.002\,\mathrm{Mpc}^{-1}$. Uncertainties are shown at 68% confidence.

| | WMAP7 alone | WMAP7 + BAO + H_0 |
|--------------------------------------|---------------------|---------------------|
| $\Omega_{\rm b}h^2$ | 0.0225 ± 0.0006 | 0.0226 ± 0.0005 |
| $\Omega_{\rm cdm} h^2$ | 0.112 ± 0.006 | 0.113 ± 0.004 |
| Ω_{Λ} | 0.73 ± 0.03 | 0.725 ± 0.016 |
| n | 0.967 ± 0.014 | 0.968 ± 0.012 |
| au | 0.088 ± 0.015 | 0.088 ± 0.014 |
| $\Delta_{\mathcal{R}}^2 \times 10^9$ | 2.43 ± 0.11 | 2.43 ± 0.09 |
| h | 0.704 ± 0.025 | 0.702 ± 0.014 |
| σ_8 | 0.81 ± 0.03 | 0.816 ± 0.024 |
| $\Omega_{\mathrm{m}}h^{2}$ | 0.134 ± 0.006 | 0.135 ± 0.004 |
| | | • |

If the assumption of spatial flatness is lifted, it turns out that WMAP7 on its own only weakly constrains the spatial curvature, due to a parameter degeneracy in the angular-diameter distance. However inclusion of other data readily removes this, e.g., inclusion of BAO and H_0 data, plus the assumption that the dark energy is a cosmological constant, yields a constraint on $\Omega_{\rm tot} \equiv \sum \Omega_i + \Omega_\Lambda$ of $\Omega_{\rm tot} = 1.002 \pm 0.011$ [3]. Results of this type are normally taken as justifying the restriction to flat cosmologies.

The baryon density $\Omega_{\rm b}$ is now measured with quite high accuracy from the CMB and large-scale structure, and is consistent with the determination from BBN; Fields and Sarkar in this volume quote the range $0.019 \leq \Omega_{\rm b}h^2 \leq 0.024$ (95% confidence).

While Ω_{Λ} is measured to be non-zero with very high confidence, there is no evidence of evolution of the dark energy density. The WMAP team find the constraint $w=-0.98\pm0.05$ on a constant equation of state from a compilation of data including SNe Ia, with the cosmological constant case w=-1 giving an excellent fit to the data. Allowing more complicated forms of dark energy weakens the limits.

The data provide strong support for the main predictions of the simplest inflation models: spatial flatness and adiabatic, Gaussian, nearly scale-invariant density perturbations. But it is disappointing that there is no sign of primordial gravitational waves, with WMAP7 alone providing only an upper limit r < 0.36 at 95% confidence [2] (this assumes no running, weakening to 0.49 if running is allowed). The spectral index n is placed in an interesting position, with indications that n < 1 is required by the data. However, the confidence with which n = 1 is ruled out is still rather weak, and in our view it is premature to conclude that n = 1 is no longer viable.

Tests have been made for various types of non-Gaussianity, a particular example being a parameter $f_{\rm NL}$ which measures a quadratic contribution to the perturbations. Various non-gaussianity shapes are possible (see Ref. 3 for details), and current constraints on the popular 'local', 'equilateral', and 'orthogonal' types are $-10 < f_{\rm NL}^{\rm local} < 74$,

 $-210 < f_{\rm NL}^{\rm equil} < 270,$ and $-410 < f_{\rm NL}^{\rm orthog} < 6$ at 95% confidence (these look weak, but prominent non-Gaussianity requires the product $f_{\rm NL}\Delta_{\mathcal{R}}$ to be large, and $\Delta_{\mathcal{R}}$ is of order $10^{-5}).$ There is presently no secure indication of primordial non-gaussianity.

One parameter which is very robust is the age of the Universe, as there is a useful coincidence that for a flat Universe the position of the first peak is strongly correlated with the age. The WMAP7 result is 13.77 ± 0.13 Gyr (assuming flatness). This is in good agreement with the ages of the oldest globular clusters and radioactive dating.

23.5. Outlook for the future

The concordance model is now well established, and there seems little room left for any dramatic revision of this paradigm. A measure of the strength of that statement is how difficult it has proven to formulate convincing alternatives.

Should there indeed be no major revision of the current paradigm, we can expect future developments to take one of two directions. Either the existing parameter set will continue to prove sufficient to explain the data, with the parameters subject to ever-tightening constraints, or it will become necessary to deploy new parameters. The latter outcome would be very much the more interesting, offering a route towards understanding new physical processes relevant to the cosmological evolution. There are many possibilities on offer for striking discoveries, for example:

- The cosmological effects of a neutrino mass may be unambiguously detected, shedding light on fundamental neutrino properties;
- Compelling detection of deviations from scale-invariance in the initial perturbations would indicate dynamical processes during perturbation generation by, for instance, inflation;
- Detection of primordial non-Gaussianities would indicate that non-linear processes influence the perturbation generation mechanism:
- Detection of variation in the dark-energy density (i.e., $w \neq -1$) would provide much-needed experimental input into the nature of the properties of the dark energy.

These provide more than enough motivation for continued efforts to test the cosmological model and improve its accuracy.

Over the coming years, there are a wide range of new observations which will bring further precision to cosmological studies. Indeed, there are far too many for us to be able to mention them all here, and so we will just highlight a few areas.

The CMB observations will improve in several directions. A current frontier is the study of polarization, first detected in 2002 by DASI and for which power spectrum measurements have now been made by several experiments. Future measurements may be able to separately detect the two modes of polarization. Another area of development is pushing accurate power spectrum measurements to smaller angular scales, currently well underway with ACT and SPT. Finally, we mention the *Planck* satellite, launched in 2009, which is making high-precision all-sky maps of temperature and polarization, utilizing a very wide frequency range to improve understanding of foreground contaminants, and to compile a large sample of clusters via the Sunyaev–Zel'dovich effect. Its main cosmological results will be published in early 2013.

An impressive array of ground-based dark energy surveys are also already operational, under construction, or proposed, including ground-based imaging surveys the Dark Energy Survey, Pan-STARRS, and LSST, spectroscopic surveys such as BigBOSS and DESpec, and proposed space missions Euclid and WFIRST.

An exciting new area for the future will be radio surveys of the redshifted 21-cm line of hydrogen. Because of the intrinsic narrowness of this line, by tuning of the bandpass the emission from narrow redshift slices of the Universe will be measured to extremely high redshift, probing the details of the reionization process at redshifts up to perhaps 20. LOFAR is the first instrument able to do this and is at an advanced construction and commissioning stage. In the longer term, the Square Kilometer Array (SKA) will take these studies to a precision level.

The above future surveys will address fundamental questions of physics well beyond just testing the 'concordance' Λ CDM model and minor variations. By learning about both the geometry of the universe and the growth of perturbations, it will be possible to test theories of modified gravity and inhomogeneous universes.

The development of the first precision cosmological model is a major achievement. However, it is important not to lose sight of the motivation for developing such a model, which is to understand the underlying physical processes at work governing the Universe's evolution. On that side, progress has been much less dramatic. For instance, there are many proposals for the nature of the dark matter, but no consensus as to which is correct. The nature of the dark energy remains a mystery. Even the baryon density, now measured to an accuracy of a few percent, lacks an underlying theory able to predict it even within orders of magnitude. Precision cosmology may have arrived, but at present many key questions remain to motivate and challenge the cosmology community.

24. DARK MATTER

Revised September 2011 by M. Drees (Bonn University) and G. Gerbier (Saclay, CEA).

24.1. Theory

24.1.1. Evidence for Dark Matter:

The existence of Dark (i.e., non-luminous and non-absorbing) Matter (DM) is by now well established [1,2]. The earliest, and perhaps still most convincing, evidence for DM came from the observation that various luminous objects (stars, gas clouds, globular clusters, or entire galaxies) move faster than one would expect if they only felt the gravitational attraction of other visible objects. An important example is the measurement of galactic rotation curves. The rotational velocity v of an object on a stable Keplerian orbit with radius r around a galaxy scales like $v(r) \propto \sqrt{M(r)/r}$, where M(r)is the mass inside the orbit. If r lies outside the visible part of the galaxy and mass tracks light, one would expect $v(r) \propto 1/\sqrt{r}$. Instead, in most galaxies one finds that v becomes approximately constant out to the largest values of r where the rotation curve can be measured; in our own galaxy, $v \simeq 240$ km/s at the location of our solar system, with little change out to the largest observable radius. This implies the existence of a dark halo, with mass density $\rho(r) \propto 1/r^2$, i.e., $M(r) \propto r$; at some point ρ will have to fall off faster (in order to keep the total mass of the galaxy finite), but we do not know at what radius this will happen. This leads to a lower bound on the DM mass density, $\Omega_{\rm DM} \gtrsim 0.1$, where $\Omega_X \equiv \rho_X/\rho_{\rm crit}$, $\rho_{\rm crit}$ being the critical mass density (i.e., $\Omega_{\text{tot}} = 1$ corresponds to a flat Universe).

The observation of clusters of galaxies tends to give somewhat larger values, $\Omega_{\rm DM} \simeq 0.2$. These observations include measurements of the peculiar velocities of galaxies in the cluster, which are a measure of their potential energy if the cluster is virialized; measurements of the X-ray temperature of hot gas in the cluster, which again correlates with the gravitational potential felt by the gas; and—most directly—studies of (weak) gravitational lensing of background galaxies on the cluster.

A particularly compelling example involves the bullet cluster (1E0657-558) which recently (on cosmological time scales) passed through another cluster. As a result, the hot gas forming most of the clusters' baryonic mass was shocked and decelerated, whereas the galaxies in the clusters proceeded on ballistic trajectories. Gravitational lensing shows that most of the total mass also moved ballistically, indicating that DM self-interactions are indeed weak [1].

The currently most accurate, if somewhat indirect, determination of $\Omega_{\rm DM}$ comes from global fits of cosmological parameters to a variety of observations; see the Section on Cosmological Parameters for details. For example, using measurements of the anisotropy of the cosmic microwave background (CMB) and of the spatial distribution of galaxies, Ref. 3 finds a density of cold, non-baryonic matter

$$\Omega_{\rm nbm}h^2 = 0.112 \pm 0.006 \,\,\,\,(24.1)$$

where h is the Hubble constant in units of 100 km/(s·Mpc). Some part of the baryonic matter density [3],

$$\Omega_{\rm b}h^2 = 0.022 \pm 0.001 \;, \tag{24.2}$$

may well contribute to (baryonic) DM, e.g., MACHOs [4] or cold molecular gas clouds [5].

The DM density in the "neighborhood" of our solar system is also of considerable interest. This was first estimated as early as 1922 by J.H. Jeans, who analyzed the motion of nearby stars transverse to the galactic plane [2]. He concluded that in our galactic neighborhood, the average density of DM must be roughly equal to that of luminous matter (stars, gas, dust). Remarkably enough, the most recent estimate, based on a detailed model of our galaxy constrained by a host of observables including the galactic rotation curve, finds a quite similar result for the smooth component of the local Dark Matter density [6]:

$$\rho_{\rm DM}^{\rm local} = (0.39 \pm 0.03) \frac{{\rm GeV}}{{\rm cm}^3} .$$
(24.3)

This value may have to be increased by a factor of 1.2 ± 0.2 since the baryons in the galactic disk, in which the solar system is located, also increase the local DM density [7]. Small substructures (minihaloes, streams) are not likely to change the local DM density significantly [1].

24.1.2. Candidates for Dark Matter:

Analyses of structure formation in the Universe indicate that most DM should be "cold" or "cool", i.e., should have been non-relativistic at the onset of galaxy formation (when there was a galactic mass inside the causal horizon) [1]. This agrees well with the upper bound [3] on the contribution of light neutrinos to Eq. (24.1),

$$\Omega_{\nu}h^2 < 0.0062 \quad 95\% \text{ CL}$$
 (24.4)

Candidates for non-baryonic DM in Eq. (24.1) must satisfy several conditions: they must be stable on cosmological time scales (otherwise they would have decayed by now), they must interact very weakly with electromagnetic radiation (otherwise they wouldn't qualify as dark matter), and they must have the right relic density. Candidates include primordial black holes, axions, sterile neutrinos, and weakly interacting massive particles (WIMPs).

Primordial black holes must have formed before the era of Big-Bang nucleosynthesis, since otherwise they would have been counted in Eq. (24.2) rather than Eq. (24.1). Such an early creation of a large number of black holes is possible only in certain somewhat contrived cosmological models [8].

The existence of axions [9] was first postulated to solve the strong CP problem of QCD; they also occur naturally in superstring theories. They are pseudo Nambu-Goldstone bosons associated with the (mostly) spontaneous breaking of a new global "Peccei-Quinn" (PQ) U(1) symmetry at scale f_a ; see the Section on Axions in this Review for further details. Although very light, axions would constitute cold DM, since they were produced non-thermally. At temperatures well above the QCD phase transition, the axion is massless, and the axion field can take any value, parameterized by the "misalignment angle" θ_i . At $T \lesssim 1$ GeV, the axion develops a mass m_a due to instanton effects. Unless the axion field happens to find itself at the minimum of its potential ($\theta_i = 0$), it will begin to oscillate once m_a becomes comparable to the Hubble parameter H. These coherent oscillations transform the energy originally stored in the axion field into physical axion quanta. The contribution of this mechanism to the present axion relic density is [1]

$$\Omega_a h^2 = \kappa_a \left(f_a / 10^{12} \text{ GeV} \right)^{1.175} \theta_i^2 ,$$
 (24.5)

where the numerical factor κ_a lies roughly between 0.5 and a few. If $\theta_i \sim \mathcal{O}(1)$, Eq. (24.5) will saturate Eq. (24.1) for $f_a \sim 10^{11}$ GeV, comfortably above laboratory and astrophysical constraints [9]; this would correspond to an axion mass around 0.1 meV. However, if the post-inflationary reheat temperature $T_R > f_a$, cosmic strings will form during the PQ phase transition at $T \simeq f_a$. Their decay will give an additional contribution to Ω_a , which is often bigger than that in Eq. (24.5) [1], leading to a smaller preferred value of f_a , i.e., larger m_a . On the other hand, values of f_a near the Planck scale become possible if θ_i is for some reason very small.

"Sterile" $SU(2) \times U(1)_Y$ singlet neutrinos with keV masses [10] could alleviate the "cusp/core problem" [1] of cold DM models. If they were produced non-thermally through mixing with standard neutrinos, they would eventually decay into a standard neutrino and a photon.

Weakly interacting massive particles (WIMPs) χ are particles with mass roughly between 10 GeV and a few TeV, and with cross sections of approximately weak strength. Within standard cosmology, their present relic density can be calculated reliably if the WIMPs were in thermal and chemical equilibrium with the hot "soup" of Standard Model (SM) particles after inflation. In this case, their density would become exponentially (Boltzmann) suppressed at $T < m_{\chi}$. The WIMPs therefore drop out of thermal equilibrium ("freeze out") once the rate of reactions that change SM particles into WIMPs or vice

versa, which is proportional to the product of the WIMP number density and the WIMP pair annihilation cross section into SM particles σ_A times velocity, becomes smaller than the Hubble expansion rate of the Universe. After freeze out, the co-moving WIMP density remains essentially constant; if the Universe evolved adiabatically after WIMP decoupling, this implies a constant WIMP number to entropy density ratio. Their present relic density is then approximately given by (ignoring logarithmic corrections) [11]

$$\Omega_{\chi} h^2 \simeq const. \cdot \frac{T_0^3}{M_{\rm Pl}^3 \langle \sigma_A v \rangle} \simeq \frac{0.1 \text{ pb} \cdot c}{\langle \sigma_A v \rangle} .$$
 (24.6)

Here T_0 is the current CMB temperature, $M_{\rm Pl}$ is the Planck mass, c is the speed of light, σ_A is the total annihilation cross section of a pair of WIMPs into SM particles, v is the relative velocity between the two WIMPs in their cms system, and $\langle \ldots \rangle$ denotes thermal averaging. Freeze out happens at temperature $T_F \simeq m_\chi/20$ almost independently of the properties of the WIMP. This means that WIMPs are already non-relativistic when they decouple from the thermal plasma; it also implies that Eq. (24.6) is applicable if $T_R > T_F$. Notice that the 0.1 pb in Eq. (24.6) contains factors of T_0 and $M_{\rm Pl}$; it is, therefore, quite intriguing that it "happens" to come out near the typical size of weak interaction cross sections.

The seemingly most obvious WIMP candidate is a heavy neutrino. However, an SU(2) doublet neutrino will have too small a relic density if its mass exceeds $M_Z/2$, as required by LEP data. One can suppress the annihilation cross section, and hence increase the relic density, by postulating mixing between a heavy SU(2) doublet and some sterile neutrino. However, one also has to require the neutrino to be stable; it is not obvious why a massive neutrino should not be allowed to decay.

The currently best motivated WIMP candidate is, therefore, the lightest superparticle (LSP) in supersymmetric models [12] with exact R-parity (which guarantees the stability of the LSP). Searches for exotic isotopes [13] imply that a stable LSP has to be neutral. This leaves basically two candidates among the superpartners of ordinary particles, a sneutrino, and a neutralino. The negative outcome of various WIMP searches (see below) rules out "ordinary" sneutrinos as primary component of the DM halo of our galaxy. (In models with gauge-mediated SUSY breaking, the lightest "messenger sneutrino" could make a good WIMP [14].) The most widely studied WIMP is therefore the lightest neutralino. Detailed calculations [1] show that the lightest neutralino will have the desired thermal relic density Eq. (24.1) in at least four distinct regions of parameter space. χ could be (mostly) a bino or photino (the superpartner of the $U(1)_Y$ gauge boson and photon, respectively), if both χ and some sleptons have mass below ~ 150 GeV, or if m_{χ} is close to the mass of some sfermion (so that its relic density is reduced through co-annihilation with this sfermion), or if $2m_{\chi}$ is close to the mass of the *CP*-odd Higgs boson present in supersymmetric models. Finally, Eq. (24.1) can also be satisfied if χ has a large higgsino or wino component.

Many non-supersymmetric extensions of the Standard Model also contain viable WIMP candidates [1]. Examples are the lightest T-odd particle in "Little Higgs" models with conserved T-parity, or "techni-baryons" in scenarios with an additional, strongly interacting ("technicolor" or similar) gauge group.

There also exist models where the DM particles, while interacting only weakly with ordinary matter, have quite strong interactions within an extended "dark sector" of the theory. These were motivated by measurements by the PAMELA, ATIC and Fermi satellites indicating excesses in the cosmic e^+ and/or e^- fluxes at high energies. However, these excesses are relative to background estimates that are clearly too simplistic (e.g., neglecting primary sources of electrons and positrons, and modeling the galaxy as a homogeneous cylinder). Moreover, the excesses, if real, are far too large to be due to usual WIMPs, but can be explained by astrophysical sources. It therefore seems unlikely that they are due to Dark Matter [15]. Similarly, claims of positive signals for direct WIMP detection by the DAMA and, more recently, CoGeNT and CRESST collaborations (see below) led to the development of tailor-made models to alleviate tensions with null experiments. Since we are not convinced that these data indeed signal WIMP detection, and these models (some of which were quickly excluded by improved measurements) lack independent motivation, we will not discuss them any further in this Review.

Although thermally produced WIMPs are attractive DM candidates because their relic density naturally has at least the right order of magnitude, non-thermal production mechanisms have also been suggested, e.g., LSP production from the decay of some moduli fields [16], from the decay of the inflaton [17], or from the decay of "Q-balls" (non-topological solitons) formed in the wake of Affleck-Dine baryogenesis [18]. Although LSPs from these sources are typically highly relativistic when produced, they quickly achieve kinetic (but not chemical) equilibrium if T_R exceeds a few MeV [19](but stays below $m_{\chi}/20$). They therefore also contribute to cold DM. Finally, if the WIMPs aren't their own antiparticles, an asymmetry between WIMPs and antiWIMPs might have been created in the early Universe, possibly by the same (unknown) mechanism that created the baryon antibaryon asymmetry. In such "asymmetric DM" models [20] the WIMP anti-WIMP annihilation cross section $\langle \sigma_A v \rangle$ should be significantly larger than 1 pb \cdot c, cf Eq. (24.6).

Primary black holes (as MACHOs), axions, sterile neutrinos, and WIMPs are all (in principle) detectable with present or near-future technology (see below). There are also particle physics DM candidates which currently seem almost impossible to detect, unless they decay; the present lower limit on their lifetime is of order 10^{25} to 10^{26} s for 100 GeV particles. These include the gravitino (the spin-3/2 superpartner of the graviton) [1], states from the "hidden sector" thought responsible for supersymmetry breaking [14], and the axino (the spin-1/2 superpartner of the axion) [1].

24.2. Experimental detection of Dark Matter

24.2.1. The case of baryonic matter in our galaxy:

The search for hidden galactic baryonic matter in the form of MAssive Compact Halo Objects (MACHOs) has been initiated following the suggestion that they may represent a large part of the galactic DM and could be detected through the microlensing effect [4]. The MACHO, EROS, and OGLE collaborations have performed a program of observation of such objects by monitoring the luminosity of millions of stars in the Large and Small Magellanic Clouds for several years. EROS concluded that MACHOs cannot contribute more than 8% to the mass of the galactic halo [21], while MACHO observed a signal at 0.4 solar mass and put an upper limit of 40%. Overall, this strengthens the need for non-baryonic DM, also supported by the arguments developed above.

24.2.2. Axion searches:

Axions can be detected by looking for $a \to \gamma$ conversion in a strong magnetic field [1]. Such a conversion proceeds through the loop-induced $a\gamma\gamma$ coupling, whose strength $g_{a\gamma\gamma}$ is an important parameter of axion models. There currently are two experiments searching for axionic DM. They both employ high quality cavities. The cavity "Q factor" enhances the conversion rate on resonance, i.e., for $m_a(c^2 + v_a^2/2) = \hbar \omega_{\rm res}$. One then needs to scan the resonance frequency in order to cover a significant range in m_a or, equivalently, f_a . The bigger of the two experiments, the ADMX experiment [22], originally situated at the LLNL in California but now running at the University of Washington, started taking data in the first half of 1996. It now uses SQUIDs as first-stage amplifiers; their extremely low noise temperature (1.2 K) enhances the conversion signal. Published results [23], combining data taken with conventional amplifiers and SQUIDs, exclude axions with mass between 1.9 and 3.53 μeV , corresponding to $f_a \simeq 4 \cdot 10^{13}$ GeV, for an assumed local DM density of 0.45 GeV/cm³, if $g_{a\gamma\gamma}$ is near the upper end of the theoretically expected range. An about five times better limit on $g_{a\gamma\gamma}$ was achieved [24] for 1.98 $\mu eV \leq m_a \leq 2.18~\mu eV$, if a large fraction of the local DM density is due to a single flow of axions with very low velocity dispersion. The ADMX experiment is being upgraded by reducing the cavity and SQUID temperature from the current 1.2 K to about 0.1 K. This should increase the frequency scanning speed for given sensitivity by more than two orders of magnitude, or increase the sensitivity for fixed observation time.

The smaller "CARRACK" experiment now being developed in Kyoto, Japan [25] uses Rydberg atoms (atoms excited to a very high state, n=111) to detect the microwave photons that would result from axion conversion. This allows almost noise-free detection of single photons. Their ultimate goal is to probe the range between 2 and 50 μ eV with sensitivity to all plausible axion models, if axions form most of DM.

${\bf 24.2.3.} \quad Searches \ for \ keV \ Neutrinos:$

Relic keV neutrinos ν_s can only be detected if they mix with the ordinary neutrinos. This mixing leads to radiative $\nu_s \to \nu \gamma$ decays, with lifetime $\tau_{\nu_s} \simeq 1.8 \cdot 10^{21} \text{ s} \cdot (\sin \theta)^{-2} \cdot (1 \text{ keV}/m_{\nu_s})^5$, where θ is the mixing angle [10]. This gives rise to a flux of mono-energetic photons with $E_{\gamma} = m_{\nu_s}/2$, which might be observable by X-ray satellites. In the simplest case the relic ν_s are produced only by oscillations of standard neutrinos. Assuming that all lepton-antilepton asymmetries are well below 10^{-3} , the ν_s relic density can then be computed uniquely in terms of the mixing angle θ and the mass m_{ν_s} . The combination of lower bounds on m_{ν_s} from analyses of structure formation (in particular, the Ly α "forest") and upper bounds on X-ray fluxes from various (clusters of) galaxies exclude this scenario if ν_s forms all of DM. This conclusion can be evaded if ν_s forms only part of DM, and/or if there is a lepton asymmetry $\geq 10^{-3}$ (i.e. some 7 orders of magnitude above the observed baryon-antibaryon asymmetry), and/or if there is an additional source of ν_s production in the early Universe, e.g. from the decay of heavier particles [10].

24.2.4. Basics of direct WIMP search:

As stated above, WIMPs should be gravitationally trapped inside galaxies and should have the adequate density profile to account for the observed rotational curves. These two constraints determine the main features of experimental detection of WIMPs, which have been detailed in the reviews in [1].

Their mean velocity inside our galaxy relative to its center is expected to be similar to that of stars, *i.e.*, a few hundred kilometers per second at the location of our solar system. For these velocities, WIMPs interact with ordinary matter through elastic scattering on nuclei. With expected WIMP masses in the range 10 GeV to 10 TeV, typical nuclear recoil energies are of order of 1 to 100 keV.

The shape of the nuclear recoil spectrum results from a convolution of the WIMP velocity distribution, usually taken as a Maxwellian distribution in the galactic rest frame, shifted into the Earth rest frame, with the angular scattering distribution, which is isotropic to first approximation but forward-peaked for high nuclear mass (typically higher than Ge mass) due to the nuclear form factor. Overall, this results in a roughly exponential spectrum. The higher the WIMP mass, the higher the mean value of the exponential. This points to the need for low nuclear recoil energy threshold detectors.

On the other hand, expected interaction rates depend on the product of the local WIMP flux and the interaction cross section. The first term is fixed by the local density of dark matter, taken as $0.39~{\rm GeV/cm^3}$ [see Eq. (24.3)], the mean WIMP velocity, typically 220 km/s, the galactic escape velocity, typically 544 km/s [26] and the mass of the WIMP. The expected interaction rate then mainly depends on two unknowns, the mass and cross section of the WIMP (with some uncertainty [6] due to the halo model). This is why the experimental observable, which is basically the scattering rate as a function of energy, is usually expressed as a contour in the WIMP mass—cross section plane.

The cross section depends on the nature of the couplings. For non-relativistic WIMPs, one in general has to distinguish spin-independent and spin-dependent couplings. The former can involve scalar and vector WIMP and nucleon currents (vector currents are absent for Majorana WIMPs, e.g., the neutralino), while the latter involve axial vector currents (and obviously only exist if χ carries spin). Due to coherence effects, the spin-independent cross section scales approximately as the square of the mass of the nucleus, so higher mass nuclei, from Ge to Xe, are preferred for this search. For spin-dependent coupling, the cross section depends on the nuclear spin factor; used target nuclei include ¹⁹F, ²³Na, ⁷³Ge, ¹²⁷I, ¹²⁹Xe, ¹³¹Xe, and ¹³³Cs.

Cross sections calculated in MSSM models [27] induce rates of at most 1 evt $\mathrm{day}^{-1}~\mathrm{kg}^{-1}$ of detector, much lower than the usual radioactive backgrounds. This indicates the need for underground laboratories to protect against cosmic ray induced backgrounds, and for the selection of extremely radio-pure materials.

The typical shape of exclusion contours can be anticipated from this discussion: at low WIMP mass, the sensitivity drops because of the detector energy threshold, whereas at high masses, the sensitivity also decreases because, for a fixed mass density, the WIMP flux decreases $\propto 1/m_{\chi}$. The sensitivity is best for WIMP masses near the mass of the recoiling nucleus.

Two important points are to be kept in mind when comparing exclusion curves from various experiments between them or with positive indications of a signal.

For an experiment with a fixed nuclear recoil energy threshold, the lower is the considered WIMP mass, the lower is the fraction of the spectrum to which the experiment is sensitive. This fraction may be extremely small in some cases. For instance CoGeNT [28], using a Germanium detector with an energy threshold of around 2 keV, is sensitive to about 10 % of the total recoil spectrum of a 7 GeV WIMP, while for XENON100 [29], using a liquid Xenon detector with a threshold of 8.4 keV, this fraction is only 0.05 % (that is the extreme tail of the distribution), for the same WIMP mass. The two experiments are then sensitive to very different parts of the WIMP velocity distribution.

A second important point to consider is the energy resolution of the detector. Again at low WIMP mass, the expected roughly exponential spectrum is very steep and when the characteristic energy of the exponential becomes of the same order as the energy resolution, the energy smearing becomes important. In particular, a significant fraction of the expected spectrum below effective threshold is smeared above threshold, increasing artificially the sensitivity. For instance, a Xenon detector with a threshold of 8 keV and infinitely good resolution is actually insensitive to a 7 GeV mass WIMP, because the expected energy distribution has a cut-off at roughly 5 keV. When folding in the experimental resolution of XENON100 (corresponding to a photostatistics of 0.5 photoelectron per keV), then around 1 % of the signal is smeared above 5 keV and 0.05 % above 8 keV. Setting reliable cross section limits in this mass range thus requires a complete understanding of the response of the detector at energies well below the nominal threshold.

In order to homogenize the reliability of the presented exclusion curves, and save the reader the trouble of performing tedious (though easy to do) calculations, we propose to set cross section limits only for WIMP mass above a "WIMP safe" minimal mass value defined as the maximum of 1) the mass where the increase of sensitivity from infinite resolution to actual experimental resolution is not more than a factor two, and 2) the mass where the experiment is sensitive to at least 1 % of the total WIMP signal recoil spectrum. These recommendations are irrespective of the content of the experimental data obtained by the experiments.

${\bf 24.2.5.} \quad {\it Status \ and \ prospects \ of \ direct \ WIMP \ searches:}$

Given the intense activity of the field, readers interested in more details than the ones given below may refer to [1], as well as to presentations at recent conferences [30].

The first searches have been performed with ultra-pure semiconductors installed in pure lead and copper shields in underground environments. Combining a priori excellent energy resolutions and very pure detector material, they produced the first limits on WIMP searches (Heidelberg-Moscow, IGEX, COSME-II, HDMS) [1]. Planned experiments using several tens of kg to a ton of Germanium run at liquid nitrogen temperature (designed for double-beta decay search)—GERDA, MAJORANA—are based in addition on passive reduction of the external and internal electromagnetic and neutron background by using segmented detectors, minimal detector housing, close electronics, pulse shape discrimination and large liquid nitrogen or argon shields. Their sensitivity to WIMP interactions will depend on their ability to lower the energy threshold sufficiently, while keeping the background rate small.

The use of so called Point Contact Germanium detectors, with a very small capacitance allowing to reach sub-keV thresholds, has given rise to new results. The CoGeNT collaboration [31] has operated a single 440 g Germanium detector with an effective threshold of 400 eV in the Soudan Underground Laboratory for 56 days [28]. After applying a rise time cut on the pulse shapes in order to remove the surface interactions known to suffer from incomplete charge collection, the resulting spectrum below 4 keV is said by the authors to exhibit an irreducible excess of events, with energy spectrum roughly exponential, compatible with a light mass WIMP in the 7-11 GeV range, and cross section around 10^{-4} pb. However, this conclusion crucially depends on the energy dependent rise time cut applied to the data and a sizeable leaking of surface events into the kept spectrum cannot be excluded. The authors acknowledge themselves that a possible instrumental effect, leading to such an excess, is worth investigating. Nevertheless, considerable attention has been paid to the WIMP interpretation, largely due to the temptation to consider it as a confirmation of the low mass WIMP DAMA/LIBRA solution, without channeling (see below). A recent unpublished analysis, presented at the TAUP 2011 conference, indicates a reduction of the claimed signal by a factor 10. Further results [32] based on data accumulated during one year led to the claim of a 2.8 sigma modulation said to be compatible with a WIMP. Here again, the claim is considerably weakened by the fact that the amplitude of the curve describing the expected WIMP modulation in the 0.5-3 keV bin is too high by roughly a factor 2 (or more, if the unmodulated "signal" has to be reduced) and wrongly leads to the conclusion that the modulation is compatible with a standard WIMP in a standard halo. This is also noted in [33].

A new consortium, CDEX/TEXONO, plans to build a 10 kg array of small and very low (200 eV) threshold detectors, and to operate them in the new Chinese Jinping underground laboratory, the deepest in the world.

In order to make further progress in the reliability of any claimed signal, active background rejection and signal identification questions have to be addressed. This is the focus of a growing number of investigations and improvements. Active background rejection in detectors relies on the relatively small ionization in nuclear recoils due to their low velocity. This induces a reduction ("quenching") of the ionization/scintillation signal for nuclear recoil signal events relative to e or γ induced backgrounds. Energies calibrated with gamma sources are then called "electron equivalent energies" (keVee unit used below). This effect has been both calculated and measured [1]. It is exploited in cryogenic detectors described later. In scintillation detectors, it induces in addition a difference in decay times of pulses induced by e/γ events vs nuclear recoils. In most cases, due to the limited resolution and discrimination power of this technique at low energies, this effect allows only a statistical background rejection. It has been used in NaI(Tl) (DAMA, LIBRA, NAIAD, Saclay NaI), in CsI(Tl) (KIMS), and Xe (ZEPLIN-I) [1,30]. Pulse shape discrimination is particularly efficient in liquid argon. Using a high energy threshold, it has been used for an event by event discrimination by the WARP experiment, but the high threshold also leads to a moderate signal sensitivity. No observation of nuclear recoils has been reported by these experiments.

Two experimental signatures are predicted for true WIMP signals. One is a strong daily forward/backward asymmetry of the nuclear recoil direction, due to the alternate sweeping of the WIMP cloud by the rotating Earth. Detection of this effect requires gaseous detectors or anisotropic response scintillators (stilbene). The second is a few percent annual modulation of the recoil rate due to the Earth speed adding to or subtracting from the speed of the Sun. This tiny effect can only be detected with large masses; nuclear recoil identification should also be performed, as the otherwise much larger background may also be subject to seasonal modulation.

The DAMA collaboration has reported results from a total of 6 years exposure with the LIBRA phase involving 250 kg of detectors, plus the earlier 6 years exposure of the original DAMA/NaI experiment with 100 kg of detectors [34], for a cumulated exposure of 1.17 t·y. They observe an annual modulation of the signal in the 2 to 6 keVee bin, with the expected period (1 year) and phase (maximum around June 2), at 8.9 σ level. If interpreted within the standard halo model described above, two possible explanations have been proposed: a

WIMP with $m_{\chi} \simeq 50$ GeV and $\sigma_{\chi p} \simeq 7 \cdot 10^{-6}$ pb (central values) or at low mass, in the 6 to 10 GeV range with $\sigma_{\chi p} \sim 10^{-3}$ pb; the cross section could be somewhat lower if there is a significant channeling effect [1].

Interpreting these observations as positive WIMP signal raises several issues of internal consistency. First, the proposed WIMP solutions would induce a sizeable fraction of nuclear recoils in the total measured rate in the 2 to 6 keVee bin. No pulse shape analysis has been reported by the authors to check whether the unmodulated signal was detectable this way. Secondly, the residual e/γ -induced background, inferred by subtracting the signal predicted by the WIMP interpretation from the data, has an unexpected shape [35], starting near zero at threshold and quickly rising to reach its maximum near 3 to 3.5 keVee; from general arguments one would expect the background (e.g. due to electronic noise) to increase towards the threshold. Finally, the amplitude of the annual modulation shows a somewhat troublesome tendency to decrease with time. The original DAMA data, taken 1995 to 2001, gave an amplitude of the modulation of 20.0 ± 3.2 in units of 10^{-3} counts/(kg·day·keVee), in the 2-6 keVee bin. During the first phase of DAMA/LIBRA, covering data taken between 2003 and 2007, this amplitude became 10.7 ± 1.9 , and in the second phase of DAMA/LIBRA, covering data taken between 2007 and 2009, it further decreased to 8.5 ± 2.2 . The ratio of amplitudes inferred from the DAMA/LIBRA phase 2 and original DAMA data is 0.43 ± 0.13 , differing from the expected value of 1 by more than 4 standard deviations. (The results for the DAMA/LIBRA phase 2 have been calculated by us using published results for the earlier data alone [36] as well as for the latest grand total [34].) Similar conclusions can be drawn from analyses of the 2-4 and 2-5 keVee bins.

Concerning compatibility with other experiments (see below), the high mass solution is clearly excluded by several null observations (CDMS, EDELWEISS, XENON), while possibly a small parameter space remains available for the low mass solution (according to [35] this possibility is excluded if the energy spectrum measured by DAMA/LIBRA is taken into account). It should be noted that these comparisons have to make assumptions about the WIMP velocity distribution (see above), but varying this within reasonable limits does not resolve the tension [35]. Moreover, one usually assumes that the WIMP scatters elastically, and that the spin-independent cross section for scattering off protons and neutrons is roughly the same. These assumptions are satisfied by all models we know that are either relatively simple (i.e. do not introduce many new particles) or have independent motivation (e.g. attempting to solve the hierarchy problem). As noted earlier, recently models have been constructed where these assumptions do not hold, but at least some of these are no longer able to make the WIMP interpretation of the DAMA(/LIBRA) observations compatible with all null results from other experiments. Finally, appealing to spin-dependent interactions does not help, either [37], in view of null results from direct searches as well as limits on neutrino fluxes from the Sun (see the subsection on indirect WIMP detection below).

No other annual modulation analysis with comparable sensitivity has been reported by any experiment. ANAIS [30], a 100 kg NaI(Tl) project planned to be run at the Canfranc lab, is in the phase of crystal selection and purification. DM-ice is a new project with the aim of checking the DAMA/LIBRA modulation signal in the southern hemisphere. It will consist of 250 kg of NaI(Tl) installed in the heart of the IceCube array. The counting rate of crystals from the previous NAIAD array recently measured in situ is currently dominated by internal radioactivity.

KIMS [38], an experiment operating 12 crystals of CsI(Tl) with a total mass of 104.4 kg in the Yang Yang laboratory in Korea, has accumulated several years of continuous operation. They should soon be able to set an upper limit on annual modulation amplitude lower than DAMA value if no annual modulation is present, or confirm the DAMA value at 3 $\sigma.$

At mK temperature, the simultaneous measurement of the phonon and ionization signals in semiconductor detectors permits event by event discrimination between nuclear and electronic recoils down to 5 to 10 keV recoil energy. This feature is being used by the CDMS [30] and EDELWEISS [30] collaborations. Surface interactions,

exhibiting incomplete charge collection, are an important residual background, which is treated by two different techniques: CDMS uses the timing information of the phonon pulse, while EDELWEISS uses the ionization pulses in an interleaved electrodes scheme. New limits on the spin-independent coupling of WIMPs were obtained by CDMS, after operating 19 Germanium cryogenic detectors at the Soudan mine during new runs involving a total exposure of around 612 kg·d (around 300 kg·d fiducial) [39]. Two events were found in the pre-defined signal region, while 0.9 background event were expected. Given these figures, no observation of a signal is claimed. While this data set alone provided a worse limit than the previous runs, the combined data sets provide an improved upper limit on the spin-independent cross section for the scattering of a 70 GeV/c² WIMP on a nucleon of 3.8×10^{-8} pb, at 90% CL. The "WIMP safe" minimal mass (see the discussion at the end of sec. 1.2.4) of this analysis is about 12 GeV.

An independent analysis of data at low energy (i.e. above 2 keV recoil energy) has also been performed by CDMS [40]. From the knowledge of the quenching factor of Germanium recoils down to 2 keV recoil energy, the energy spectrum is reconstructed using only the measured phonon energy. The obtained spectrum, once corrected for quenching, has a shape somewhat similar to that reported by CoGeNT, but with a lower amplitude (especially for one of the detector modules, which was used to set the limit) so that CDMS concludes that their data are inconsistent with the original WIMP interpretation of the CoGeNT data (note that both detectors use the same target material, so this comparison really is model-independent), as well as with the standard WIMP interpretation of the DAMA data. New detectors with interleaved electrode schemes are being built.

EDELWEISS has operated ten 400 g Germanium detectors equipped with different thermal sensors and an interdigitised charge collection electrode scheme, during one year at the Laboratoire Souterrain de Modane [41]. A total of 5 events were observed in the signal region for a fiducial exposure of 384 kg·d, while 3 events were expected from backgrounds. No WIMP signal was claimed. A similar sensitivity to CDMS is obtained at high mass, while the high 20 keV analysis threshold induces a somewhat poorer limit at masses lower than 50 GeV. New larger detectors with a complete coverage of the crystal with annular electrodes, and better rejection of non-recoil events are being built.

Given their similar sensitivities, the two collaborations combined their data sets. Using a simple combination method, a gain of 1.6 relative to the best limit has been obtained at WIMP masses larger than 700 GeV, and an improved limit of 3.3×10^{-8} pb for a 90 GeV WIMP mass [42].

The cryogenic experiment CRESST [30] uses the scintillation of CaWO₄ as second variable for background discrimination. CRESST has recently submitted for publication [43] the result of the analysis of 730 kg-d exposure performed with 8 detectors. The observation of 67 events in the signal region does not match the about 40 expected background events, originating from e/ γ leakage, neutron recoils, as well as leakage from α and Pb recoils. The event excess is said to be compatible with WIMPs. A likelihood method provides two solutions, respectively for 12 and 25 GeV masses, stating also that the background hypothesis alone is more than 4 sigma away from the observed data. However, some other potential sources of background are insufficiently adressed, like "no-light" events, a category of events which previously plagued the sensitivity of this experiment.

Other inorganic scintillators are also being explored, e.g. by the ROSEBUD collaboration [30].

The experimental programs of CDMS II, EDELWEISS II and CRESST II aim at an increase of sensitivity by a factor of 10, by operating around 40 kg of detectors. The next stage SuperCDMS and EURECA-I (a combination of EDELWEISS and CRESST) projects will involve typically 150 kg of detectors. Then GEODM and EURECA-2 will turn to 1 t goals.

Noble gas detectors for dark matter detection are now being developed rapidly by several groups [1]. Dual (liquid and gas) phase detectors allow to measure both the primary scintillation and the ionization electrons drifted through the liquid and amplified in the gas, which is used for background rejection.

The XENON collaboration [30] has successfully operated the 161 kg XENON100 setup at Gran Sasso laboratory during a 100 day data taking period. Within a fiducial mass of 48 kg, 3 events were observed in the signal region, while 1.8 were expected, out of which 1.2 originate from a sizeable contamination of Krypton 85 in the liquid [29]. This allowed to set the best limits at all masses on spin-independent interactions of WIMPs, with a minimum of cross section at 7.0×10^{-9} pb for a mass of 50 GeV. However, the reliability of limits set at masses lower than 10 GeV, especially wrt the relative light efficiency factor, have been discussed in the community. Moreover, as underlined near the end of section 1.2.4, the limits at low mass can be set only thanks to the poor energy resolution at threshold -8.4 keV- due to the low photoelectron yield of 0.5 pe/keV. With infinite energy resolution, a Xe detector with the same threshold of 8.4 keV is not sensitive to a WIMP mass of 7 GeV. Folding in the XENON100 resolution, the expected fraction of a 7 GeV WIMP signal above 8.4 keV is around 0.05 % (in strong contrast with the 10 % to which CoGeNT is sensitive). If one follows the recommendation made above, the "WIMP safe" minimal mass for XENON100 is around 12 GeV.

A reanalysis of part of the XENON10 data [44], using the ionization signal only, with an ionization yield of around 3.5 electron/keV at a threshold of 1.4 keV, sets a more convincing limit in the 7 GeV range, about one order of magnitude below the original CoGeNT claim (see above). The "WIMP safe" minimal mass for this XENON10 analysis is around 5 GeV. The XENON10 limit for spin dependent WIMPs with pure neutron couplings is still the best published limit at all masses [45] (but likely to be soon superseded by an analysis of XENON100 data). XENON1t, the successor of XENON100 planned to be run at Gran Sasso lab, is in its preparation phase. One should note that, presumably, the planned increase of distance between planes of PMT's will lead to a lower photoelectron yield for scintillation light than at XENON100. This was the case when going from XENON10 (around 1 pe/keV) to XENON100 (around 0.5 pe/keV). For comparison, a 0.25 pe yield per keV would correspond to a "WIMP safe" mass of order of 20 GeV.

A new liquid Xenon based project, PANDA-X, with pancake geometry, planned to be housed in the new Jinping lab, will perform a dedicated low mass WIMP search.

ZEPLIN III [30], using a similar principle and with an active mass of 12 kg of Xenon, operated in the Boulby laboratory, has been upgraded for a lower background, has acquired new data, and is now stopped. XMASS [30] in Japan is close to operate a single-phase 800 kg detector (100 kg fiducial mass) installed in a large pure water shield at the SuperKamiokande site. With no pulse shape analysis, the expected performance relies heavily on the self-shielding effect to lower the background [1].

The LUX detector [1], a 300 kg double phase Xenon detector, planned to be operated in the new SURF (previous Sanford) laboratory in US, is in the commissioning phase, in a water shield at surface, before transport underground to the 4850 level.

The WARP collaboration [30] is currently installing a 100 l Argon detector at the Gran Sasso laboratory. Thanks to a double-background rejection method based on the asymmetry between scintillating and ionizing pulses and extremely efficient pulse shape discrimination of scintillating pulses, it looks possible to achieve very high background rejection, even in the presence of the radioactive isotope ³⁹Ar. The ArDM project [30] is using a similar technique with a much larger (1,100 kg) mass. It should be installed soon and take data at the newly opened Canfranc laboratory. MiniCLEAN and DEAP-3600 [30], both measuring only scintillation signals in spherical geometries in single phase mode, are being assembled at SNOLab and will operate respectively 500 kg of Ar/Ne and 3600 kg of Ar [1]. DARK SIDE [30], is another Argon based, double phase project, involving in a first step about 50 kg of ³⁹Ar depleted Argon, to be installed in Gran Sasso lab.

The low pressure Time Projection Chamber technique is the only convincing way to measure the direction of nuclear recoils and prove the galactic origin of a possible signal [1]. The DRIFT collaboration [30] has operated a 1 $\rm m^3$ volume detector in the UK Boulby mine. Though the background due to internal radon contamination was lowered, no new competitive limit has yet been

set. The MIMAC collaboration [30] is investigating a sub-keV energy threshold TPC detector. Additional sensitive measurements of Fluor nuclei quenching factor and recoil imaging have been performed recently by this group down to few keV. A 2.5 l 1000 channel prototype is going to be operated soon in the Fréjus laboratory. Other groups developing similar techniques, though with lower sensitivity, are DMTPC in the US and NewAge in Japan.

The following more unconventional detectors use ¹⁹F nuclei to set limits on the spin dependent coupling of WIMPs, with less than kg mass detectors. The bubble chamber like detector, COUPP [30], run at Fermilab, has provided a new limit [46] for spin dependent proton coupling WIMPs for masses above 20 GeV, superseding an earlier KIMS result. PICASSO [30], a superheated droplet detector run at SNOLAB, obtained a better limit below 20 GeV on the same type of WIMPs [47]. Finally, SIMPLE [30], a similar experiment run at Laboratoire Souterrain de Rustrel, submitted results for publication that claim to provide the currently best limit on the spin-dependent WIMP-proton cross section for all WIMP masses [48].

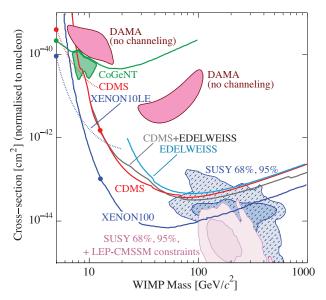

Figure 24.1: Cross sections (normalised to nucleon assuming A^2 dependence, see section 1.2.4) for spin independent coupling versus mass diagrams. References to the experimental results are given in the text. The big dots on some curves show the "WIMP safe" minimal mass for the corresponding experimental result (see details in text). DAMA candidates region (no channeling) are from [50], shaded 68% and 95% regions are SUSY predictions by [51], together with recent constraints (crosshatched 68% and 95% regions) set by LHC experiments (CMSSM) [52]. Here equal cross sections for scattering from protons and neutrons have been assumed.

Figures 24.1 and 24.2 illustrate the limits and positive claims forf cross sections, normalised to nucleon, for spin independent and spin dependent couplings, respectively, as functions of WIMP mass, where only the two currently best limits are presented. Also shown are constraints from indirect observations (see the next section) and typical regions of SUSY models, before and after recent LHC results. These figures have been made with the dmtools web page, thanks to the very efficient collaboration of dmtools team [55].

Sensitivities down to $\sigma_{\chi p}$ of 10^{-10} pb, as needed to probe large regions of MSSM parameter space [27], will be reached with detectors of typical masses of 1 ton, assuming nearly perfect background discrimination capabilities. Note that the expected WIMP rate is then 5 evts/ton/year for Ge. The ultimate neutron background will only be identified by its multiple interactions in a finely segmented or multiple-interaction-sensitive detector, and/or by operating detectors containing different target materials within the same set-up. Larger mass projects are envisaged by the DARWIN European consortium

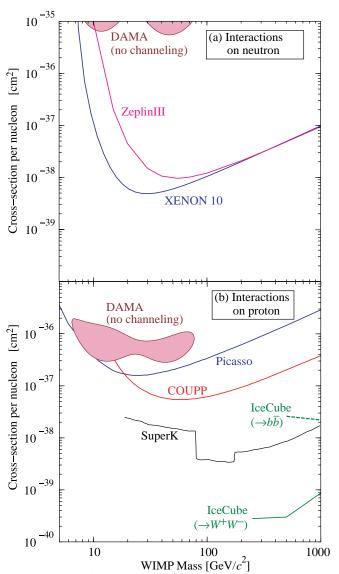

Figure 24.2: Cross sections for spin dependent coupling versus mass diagrams. References to the experimental results are given in the text. The DAMA candidates region (no channeling) are from [50]: (a) interactions on neutron; (b) interactions on proton.

and the MAX project in the US (liquid Xe and Ar multiton project) [30].

24.2.6. Status and prospects of indirect WIMP searches:

WIMPs can annihilate and their annihilation products can be detected; these include neutrinos, gamma rays, positrons, antiprotons, and antinuclei [1]. These methods are complementary to direct detection and might be able to explore higher masses and different coupling scenarios. "Smoking gun" signals for indirect detection are GeV neutrinos coming from the center of the Sun or Earth, and monoenergetic photons from WIMP annihilation in space.

WIMPs can be slowed down, captured, and trapped in celestial objects like the Earth or the Sun, thus enhancing their density and their probability of annihilation. This is a source of muon neutrinos which can interact in the Earth. Upward going muons can then be detected in large neutrino telescopes such as MACRO, BAKSAN, SuperKamiokande, Baikal, AMANDA, ANTARES, NESTOR, and the large sensitive area IceCube [1]. The best upper limit for relatively soft muons, of $\simeq 1000~{\rm muons/km^2/year}$ for muons with energy above $\sim 2~{\rm GeV}$ [53], comes from SuperKamiokande [30] using through-going muons. For more energetic muons a slightly more stringent limit

has been set by IceCube22 (using 22 strings), e.g. excluding a flux above 610 muons/km²/year from the Sun for a WIMP model with average muon energy of 150 GeV [54]. In the framework of the MSSM and with standard halo velocity profiles, only the limits from the Sun, which mostly probe spin-dependent couplings, are competitive with direct WIMP search limits. IceCube80 [30] will increase this sensitivity by a factor $\simeq 5$ at masses higher than 200 GeV while IceCube Deep Core will allow to reach masses down to 50 GeV [1].

WIMP annihilation in the halo can give a continuous spectrum of gamma rays and (at one-loop level) also monoenergetic photon contributions from the $\gamma\gamma$ and γZ channels. These channels also allow to search for WIMPs for which direct detection experiments have little sensitivity, e.g., almost pure higgsinos. However, the size of this signal depends very strongly on the halo model, but is expected to be most prominent near the galactic center. The central region of our galaxy hosts a strong TeV point source discovered [56] by the H.E.S.S. Cherenkov telescope [57]. Moreover, FERMI/LAT [30] data revealed a new extended source of GeV photons near the galactic center above and below the galactic plane [58]. Both of these sources are most likely of astrophysical origin. The presence of these unexpected backgrounds makes it more difficult to discover WIMPs in this channel, and no convincing signal has been claimed. FERMI/LAT observations of the galactic halo are in agreement with predictions based on purely astrophysical sources (in contrast to a re-analysis of earlier EGRET data [59]), and rule out many WIMP models that were constructed to explain the PAMELA and FERMI/LAT excesses in the e^{\pm} channel [60]. Similarly, Cherenkov telescope and FERMI/LAT observations of nearby dwarf galaxies, globular clusters, and clusters of galaxies only yielded upper limits on photon fluxes from WIMP annihilation. While limits from individual observations are still above the predictions of most WIMP models, a very recent combination [61] of limits from dwarf galaxies excludes WIMPs annihilating hadronically with the standard cross section needed for thermal relics, if the WIMP mass is below 25 GeV; assumptions are annihilation from an S-wave initial state, and a dark matter density distribution scaling like the inverse of the distance from the center of the dwarf galaxy at small radii.

Antiparticles arise as additional WIMP annihilation products in the halo. To date the best measurement of the antiproton flux comes from the PAMELA satellite [30], and covers kinetic energies between 60 MeV and 180 GeV [62]. The result is in good agreement with secondary production and propagation models. These data exclude WIMP models that attempt to explain the e^\pm excesses via annihilation into W^\pm or Z^0 boson pairs; however, largely due to systematic uncertainties they do not significantly constrain conventional WIMP models.

The best measurements of the positron (and electron) flux at (tens of) GeV energies again comes from PAMELA [63], showing a rather marked rise of the positron fraction between 10 and 100 GeV. The observed spectrum falls within the one order of magnitude span (largely due to differences in the propagation model used) of positron fraction values predicted by secondary production models [64]. Measurements of the total electron+positrons energy spectrum by ATIC [65], FERMI/LAT [66] and H.E.S.S. [67] between 100 and 1000 GeV also exceed the predicted purely secondary spectrum, but with very large dispersion of the magnitude of these excesses. While it has been recognized that astrophysical sources may account for all these features, many ad-hoc Dark Matter models have been built to account for these excesses. As mentioned in section 1, given the amount of jerking and twisting needed to build such models not to contradict any observation, it seems very unlikely that Dark Matter is at the origin of these excesses.

Last but not least, an antideuteron signal [1], as potentially observable by AMS2 or PAMELA, could constitute a signal for WIMP annihilation in the halo.

An interesting comparison of respective sensitivities to MSSM parameter space of future direct and various indirect searches has been performed with the DARKSUSY tool [68]. A web-based up-to-date collection of results from direct WIMP searches, theoretical predictions, and sensitivities of future experiments can be found in [55]. Also, the web page [69] allows to make predictions for WIMP

signals in various experiments, within a variety of SUSY models and to extract limits from simply parametrised data. Integrated analysis of all data from direct and indirect WIMP detection, and also from LHC experiments should converge to a comprehensive approach, required to fully unravel the mysteries of dark matter.

25. COSMIC MICROWAVE BACKGROUND

Revised August 2011 by D. Scott (University of British Columbia) and G.F. Smoot (UCB/LBNL).

25.1. Introduction

The energy content in radiation from beyond our Galaxy is dominated by the cosmic microwave background (CMB), discovered in 1965 [1]. The spectrum of the CMB is well described by a blackbody function with $T=2.7255\,\mathrm{K}$, this spectral form being one of the main pillars of the hot Big Bang model for the early Universe. The lack of any observed deviations from a blackbody spectrum constrains physical processes over cosmic history at redshifts $z\lesssim10^7$ (see earlier versions of this review). All viable cosmological models predict a very nearly Planckian spectrum inside the current observational limits.

Another observable quantity inherent in the CMB is the variation in temperature (or intensity) from one part of the microwave sky to another [2]. Since the first detection of these anisotropies by the COBE satellite [3], there has been intense activity to map the sky at increasing levels of sensitivity and angular resolution by ground-based and balloon-borne measurements. These were joined in 2003 by the first results from NASA's Wilkinson Microwave Anisotropy Probe (WMAP) [4], which were improved upon by analysis of the 3-year, 5-year, and 7-year WMAP data [5,6,7]. Together these observations have led to a stunning confirmation of the 'Standard Model of Cosmology.' In combination with other astrophysical data, the CMB anisotropy measurements place quite precise constraints on a number of cosmological parameters, and have launched us into an era of precision cosmology. This is expected to continue with the improved capabilities of ESA's Planck satellite [8,9].

25.2. Description of CMB Anisotropies

Observations show that the CMB contains anisotropies at the 10^{-5} level, over a wide range of angular scales. These anisotropies are usually expressed by using a spherical harmonic expansion of the CMB sky:

$$T(\theta, \phi) = \sum_{\ell m} a_{\ell m} Y_{\ell m}(\theta, \phi).$$

The vast majority of the cosmological information is contained in the temperature 2-point function, *i.e.*, the variance as a function only of angular separation, since we notice no preferred direction. Equivalently, the power per unit $\ln \ell$ is $\ell \sum_m |a_{\ell m}|^2 / 4\pi$.

25.2.1. The Monopole:

The CMB has a mean temperature of $T_{\gamma}=2.7255\pm0.0006\,\mathrm{K}$ (1σ) [10], which can be considered as the monopole component of CMB maps, $a_{00}.$ Since all mapping experiments involve difference measurements, they are insensitive to this average level. Monopole measurements can only be made with absolute temperature devices, such as the FIRAS instrument on the COBE satellite [11]. Such measurements of the spectrum are consistent with a blackbody distribution over more than three decades in frequency (with some recent evidence for deviation at low frequencies [12]) . A blackbody of the measured temperature corresponds to $n_{\gamma}=(2\zeta(3)/\pi^2)\,T_{\gamma}^3\simeq411\,\mathrm{cm}^{-3}$ and $\rho_{\gamma}=(\pi^2/15)\,T_{\gamma}^4\simeq4.64\times10^{-34}\,\mathrm{g\,cm}^{-3}\simeq0.260\,\mathrm{eV\,cm}^{-3}.$

25.2.2. The Dipole:

The largest anisotropy is in the $\ell=1$ (dipole) first spherical harmonic, with amplitude $3.355\pm0.008\,\mathrm{mK}$ [6]. The dipole is interpreted to be the result of the Doppler shift caused by the solar system motion relative to the nearly isotropic blackbody field, as broadly confirmed by measurements of the radial velocities of local galaxies (although with some debate [13]) . The motion of an observer with velocity $\beta\equiv v/c$ relative to an isotropic Planckian radiation field of temperature T_0 produces a Doppler-shifted temperature pattern

$$T(\theta) = T_0 (1 - \beta^2)^{1/2} / (1 - \beta \cos \theta)$$

$$\simeq T_0 \left(1 + \beta \cos \theta + \left(\beta^2 / 2 \right) \cos 2\theta + O\left(\beta^3 \right) \right).$$

At every point in the sky, one observes a blackbody spectrum, with temperature $T(\theta)$. The spectrum of the dipole is the differential of a blackbody spectrum, as confirmed by Ref. 14.

The implied velocity for the solar system barycenter is $v=369.0\pm0.9\,\mathrm{km\,s^{-1}}$, assuming a value $T_0=T_\gamma$, towards $(\ell,b)=(263.99^\circ\pm0.14^\circ,48.26^\circ\pm0.03^\circ)$ [6,15]. Such a solar system motion implies a velocity for the Galaxy and the Local Group of galaxies relative to the CMB. The derived value is $v_{\mathrm{LG}}=627\pm22\,\mathrm{km\,s^{-1}}$ towards $(\ell,b)=(276^\circ\pm3^\circ,30^\circ\pm3^\circ)$, where most of the error comes from uncertainty in the velocity of the solar system relative to the Local Group.

The dipole is a frame-dependent quantity, and one can thus determine the 'absolute rest frame' as that in which the CMB dipole would be zero. Our velocity relative to the Local Group, as well as the velocity of the Earth around the Sun, and any velocity of the receiver relative to the Earth, is normally removed for the purposes of CMB anisotropy study.

25.2.3. Higher-Order Multipoles:

The variations in the CMB temperature maps at higher multipoles $(\ell \geq 2)$ are interpreted as being mostly the result of perturbations in the density of the early Universe, manifesting themselves at the epoch of the last scattering of the CMB photons. In the hot Big Bang picture, the expansion of the Universe cools the plasma so that by a redshift $z \simeq 1100$ (with little dependence on the details of the model), the hydrogen and helium nuclei can bind electrons into neutral atoms, a process usually referred to as recombination [16]. Before this epoch, the CMB photons are tightly coupled to the baryons, while afterwards they can freely stream towards us.

Theoretical models generally predict that the $a_{\ell m}$ modes are Gaussian random fields to high precision, e.g., standard slow-roll inflation's non-Gaussian contribution is expected to be one or two orders of magnitude below current observational limits [17]. Although non-Gaussianity of various forms is possible in early Universe models, tests show that Gaussianity is an extremely good simplifying approximation [18], with only some relatively weak indications of non-Gaussianity or statistical anisotropy at large scales. Such signatures found in existing WMAP data are generally considered to be subtle foreground or instrumental artifacts [19].

A statistically isotropic sky means that all m's are equivalent, i.e., there is no preferred axis. Together with the assumption of Gaussian statistics, the variance of the temperature field (or equivalently the power spectrum in ℓ) then fully characterizes the anisotropies. The power summed over all m's at each ℓ is $(2\ell+1)C_\ell/(4\pi)$, where $C_\ell \equiv \langle |a_{\ell m}|^2 \rangle$. Thus averages of $a_{\ell m}$'s over m can be used as estimators of the C_ℓ 's to constrain their expectation values, which are the quantities predicted by a theoretical model. For an idealized full-sky observation, the variance of each measured C_ℓ (i.e., the variance of the variance) is $[2/(2\ell+1)]C_\ell^2$. This sampling uncertainty (known as 'cosmic variance') comes about because each C_ℓ is χ^2 distributed with $(2\ell+1)$ degrees of freedom for our observable volume of the Universe. For fractional sky coverage, $f_{\rm sky}$, this variance is increased by $1/f_{\rm sky}$ and the modes become partially correlated.

It is important to understand that theories predict the expectation value of the power spectrum, whereas our sky is a single realization. Hence the cosmic variance is an unavoidable source of uncertainty when constraining models; it dominates the scatter at lower ℓ 's, while the effects of instrumental noise and resolution dominate at higher ℓ 's [20].

25.2.4. Angular Resolution and Binning:

There is no one-to-one conversion between multipole ℓ and the angle subtended by a particular spatial scale projected onto the sky. However, a single spherical harmonic $Y_{\ell m}$ corresponds to angular variations of $\theta \sim \pi/\ell$. CMB maps contain anisotropy information from the size of the map (or in practice some fraction of that size) down to the beam-size of the instrument, σ . One can think of the effect of a Gaussian beam as rolling off the power spectrum with the function $\mathrm{e}^{-\ell(\ell+1)\sigma^2}$.

For less than full sky coverage, the ℓ modes become correlated. Hence, experimental results are usually quoted as a series of 'band powers', defined as estimators of $\ell(\ell+1)C_\ell/2\pi$ over different ranges of ℓ . Because of the strong foreground signals in the Galactic Plane, even 'all-sky' surveys, such as WMAP and Planck involve a cut sky. The amount of binning required to obtain uncorrelated estimates of power also depends on the map size.

25.3. Cosmological Parameters

The current 'Standard Model' of cosmology contains around 10 free parameters (see The Cosmological Parameters—Sec. 23 of this Review). The basic framework is the Friedmann-Robertson-Walker (FRW) metric (i.e., a universe that is approximately homogeneous and isotropic on large scales), with density perturbations laid down at early times and evolving into today's structures (see Big-Bang cosmology—Sec. 21 of this Review). The most general possible set of density variations is a linear combination of an adiabatic density perturbation and some isocurvature perturbations. Adiabatic means that there is no change to the entropy per particle for each species, i.e., $\delta\rho/\rho$ for matter is $(3/4)\delta\rho/\rho$ for radiation. Isocurvature means that the set of individual density perturbations adds to zero, for example, matter perturbations compensate radiation perturbations so that the total energy density remains unperturbed, i.e., $\delta \rho$ for matter is $-\delta \rho$ for radiation. These different modes give rise to distinct (temporal) phases during growth, with those of the adiabatic scenario being strongly preferred by the data. Models that generate mainly isocurvature type perturbations (such as most topological defect scenarios) are no longer considered to be viable. However, an admixture of the adiabatic mode with up to about 10% isocurvature contribution is still allowed [21].

Within the adiabatic family of models, there is, in principle, a free function describing the variation of comoving curvature perturbations, $\mathcal{R}(\mathbf{x},t)$. The great virtue of \mathcal{R} is that it is constant in time for a purely adiabatic perturbation. There are physical reasons to anticipate that the variance of these perturbations will be described well by a power-law in scale, i.e., in Fourier space $\langle |\mathcal{R}|_k^2 \rangle \propto k^{n-4}$, where k is wavenumber and n is the usual definition of spectral index. So-called 'scale-invariant' initial conditions (meaning gravitational potential fluctuations which are independent of k) correspond to n = 1. In inflationary models [22], perturbations are generated by quantum fluctuations, which are set by the energy scale of inflation, together with the slope and higher derivatives of the inflationary potential. One generally expects that the Taylor series expansion of $\ln \mathcal{R}_k(\ln k)$ has terms of steadily decreasing size. For the simplest models, there are thus two parameters describing the initial conditions for density perturbations: the amplitude and slope of the power spectrum. These can be explicitly defined, for example, through:

$$\Delta_{\mathcal{R}}^{2} \equiv (k^{3}/2\pi^{2}) \left\langle |\mathcal{R}|_{k}^{2} \right\rangle = A \left(k/k_{0} \right)^{n-1},$$

with $A \equiv \Delta_{\mathcal{R}}^2(k_0)$ and $k_0 = 0.002\,\mathrm{Mpc}^{-1}$, say. There are many other equally valid definitions of the amplitude parameter (see also Sec. 21 and Sec. 23 of this *Review*), and we caution that the relationships between some of them can be cosmology-dependent. In 'slow roll' inflationary models, this normalization is proportional to the combination $V^3/(V')^2$, for the inflationary potential $V(\phi)$. The slope n also involves V'', and so the combination of A and n can, in principle, constrain potentials.

Inflation generates tensor (gravitational wave) modes, as well as scalar (density perturbation) modes. This fact introduces another parameter, measuring the amplitude of a possible tensor component, or equivalently the ratio of the tensor to scalar contributions. The tensor amplitude is $A_{\rm T} \propto V$, and thus one expects a larger gravitational wave contribution in models where inflation happens at higher energies. The tensor power spectrum also has a slope, often denoted $n_{\rm T}$, but since this seems unlikely to be measured in the near future, it is sufficient for now to focus only on the amplitude of the gravitational wave component. It is most common to define the tensor contribution through r, the ratio of tensor to scalar perturbation spectra at some small value of k (although sometimes it is defined in terms of the ratio of contributions at $\ell=2$). Different inflationary potentials will lead to different predictions, e.g., for $\lambda \phi^4$ inflation with 50 e-folds, r=0.32, and for $m^2\phi^2$ inflation $r\simeq 0.15$, while other models can have arbitrarily small values of r. In any case, whatever the specific definition, and whether they come from inflation or something else, the 'initial conditions' give rise to a minimum of 3 parameters: A, nand r.

The background cosmology requires an expansion parameter (the Hubble Constant, H_0 , often represented through $H_0 = 100 \, h \, \mathrm{km \, s^{-1} Mpc^{-1}}$) and several parameters to describe the matter

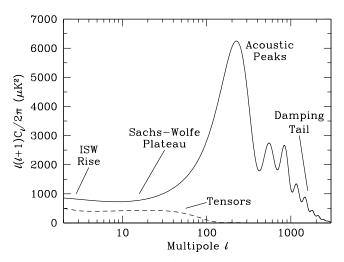

Figure 25.1: The theoretical CMB anisotropy power spectrum, using a standard Λ CDM model from CMBFAST. The x-axis is logarithmic here. The regions, each covering roughly a decade in ℓ , are labeled as in the text: the ISW rise; Sachs-Wolfe plateau; acoustic peaks; and damping tail. Also shown is the shape of the tensor (gravitational wave) contribution, with an arbitrary normalization.

and energy content of the Universe. These are usually given in terms of the critical density, *i.e.*, for species 'x', $\Omega_{\rm x} \equiv \rho_{\rm x}/\rho_{\rm crit}$, where $\rho_{\rm crit} \equiv 3H_0^2/8\pi G$. Since physical densities $\rho_{\rm x} \propto \Omega_{\rm x} h^2 \equiv \omega_{\rm x}$ are what govern the physics of the CMB anisotropies, it is these ω 's that are best constrained by CMB data. In particular CMB, observations constrain $\Omega_{\rm b}h^2$ for baryons and $\Omega_{\rm m}h^2$ for baryons plus cold dark matter.

The contribution of a cosmological constant Λ (or other form of dark energy) is usually included via a parameter which quantifies the curvature, $\Omega_{\rm K} \equiv 1-\Omega_{\rm tot}$, where $\Omega_{\rm tot} = \Omega_{\rm m} + \Omega_{\Lambda}$. The radiation content, while in principle a free parameter, is precisely enough determined by the measurement of T_{γ} , and makes a < 10^{-4} contribution to $\Omega_{\rm tot}$ today.

The main effect of astrophysical processes on the C_ℓ 's comes through reionization. The Universe became reionized at some redshift $z_{\rm i}$, long after recombination, affecting the CMB through the integrated Thomson scattering optical depth:

$$\tau = \int_0^{z_{\rm i}} \sigma_{\rm T} n_{\rm e}(z) \frac{dt}{dz} dz,$$

where $\sigma_{\rm T}$ is the Thomson cross-section, $n_{\rm e}(z)$ is the number density of free electrons (which depends on astrophysics), and dt/dz is fixed by the background cosmology. In principle, τ can be determined from the small-scale matter power spectrum, together with the physics of structure formation and feedback processes. However, this is a sufficiently intricate calculation that τ needs to be considered as a free parameter.

Thus, we have eight basic cosmological parameters: A, n, r, h, $\Omega_{\rm b}h^2$, $\Omega_{\rm m}h^2$, $\Omega_{\rm tot}$, and τ . One can add additional parameters to this list, particularly when using the CMB in combination with other data sets. The next most relevant ones might be: $\Omega_{\nu}h^2$, the massive neutrino contribution; $w \ (\equiv p/\rho)$, the equation of state parameter for the dark energy; and $dn/d\ln k$, measuring deviations from a constant spectral index. To these 11 one could of course add further parameters describing additional physics, such as details of the reionization process, features in the initial power spectrum, a sub-dominant contribution of isocurvature modes, etc.

As well as these underlying parameters, there are other quantities that can be obtained from them. Such derived parameters include the actual Ω 's of the various components (e.g., $\Omega_{\rm m}$), the variance of density perturbations at particular scales (e.g., σ_8), the age of the Universe today (t_0), the age of the Universe at recombination, reionization, etc.

25.4. Physics of Anisotropies

The cosmological parameters affect the anisotropies through the well understood physics of the evolution of linear perturbations within a background FRW cosmology. There are very effective, fast, and publicly available software codes for computing the CMB anisotropy, polarization, and matter power spectra, e.g., CMBFAST [23] and CAMB [24]. These have been tested over a wide range of cosmological parameters and are considered to be accurate to better than the 1% level [25].

A description of the physics underlying the C_{ℓ} 's can be separated into three main regions, as shown in Fig. 25.1.

25.4.1. The ISW rise, $\ell \lesssim 10$, and Sachs-Wolfe plateau, $10 \lesssim \ell \lesssim 100$:

The horizon scale (or more precisely, the angle subtended by the Hubble radius) at last scattering corresponds to $\ell \simeq 100$. Anisotropies at larger scales have not evolved significantly, and hence directly reflect the 'initial conditions'. $\delta T/T = -(1/5)\mathcal{R}(\mathbf{x}_{\rm LSS}) \simeq (1/3)\delta\phi/c^2$, here $\delta\phi$ is the perturbation to the gravitational potential, evaluated on the last scattering surface (LSS). This is a result of the combination of gravitational redshift and intrinsic temperature fluctuations and is usually referred to as the Sachs-Wolfe effect [26].

Assuming that a nearly scale-invariant spectrum of curvature and corresponding density perturbations was laid down at early times (i.e., $n \simeq 1$, meaning equal power per decade in k), then $\ell(\ell+1)C_{\ell} \simeq \text{constant}$ at low ℓ 's. This effect is hard to see unless the multipole axis is plotted logarithmically (as in Fig. 25.1, but not Fig. 25.2).

Time variation of the potentials (i.e., time-dependent metric perturbations) leads to an upturn in the C_ℓ 's in the lowest several multipoles; any deviation from a total equation of state w=0 has such an effect. So the dominance of the dark energy at low redshift makes the lowest ℓ 's rise above the plateau. This is sometimes called the integrated Sachs-Wolfe effect (or ISW rise), since it comes from the line integral of $\dot{\phi}$; it has been confirmed through correlations between the large-angle anisotropies and large-scale structure [27]. Specific models can also give additional contributions at low ℓ (e.g., perturbations in the dark energy component itself [28]), but typically these are buried in the cosmic variance.

In principle, the mechanism that produces primordial perturbations could generate scalar, vector, and tensor modes. However, the vector (vorticity) modes decay with the expansion of the Universe. The tensors (transverse trace-free perturbations to the metric) generate temperature anisotropies through the integrated effect of the locally anisotropic expansion of space. Since the tensor modes also redshift away after they enter the horizon, they contribute only to angular scales above about 1° (see Fig. 25.1). Hence some fraction of the low ℓ signal could be due to a gravitational wave contribution, although small amounts of tensors are essentially impossible to discriminate from other effects that might raise the level of the plateau. However, the tensors can be distinguished using polarization information (see Sec. 25.6).

25.4.2. The acoustic peaks, $100 \lesssim \ell \lesssim 1000$:

On sub-degree scales, the rich structure in the anisotropy spectrum is the consequence of gravity-driven acoustic oscillations occurring before the atoms in the Universe became neutral. Perturbations inside the horizon at last scattering have been able to evolve causally and produce anisotropy at the last scattering epoch, which reflects this evolution. The frozen-in phases of these sound waves imprint a dependence on the cosmological parameters, which gives CMB anisotropies their great constraining power.

The underlying physics can be understood as follows. Before the Universe became neutral, the proton-electron plasma was tightly coupled to the photons, and these components behaved as a single 'photon-baryon fluid.' Perturbations in the gravitational potential, dominated by the dark matter component, were steadily evolving. They drove oscillations in the photon-baryon fluid, with photon pressure providing most of the restoring force and baryons giving some additional inertia. The perturbations were quite small in amplitude, $O(10^{-5})$, and so evolved linearly. That means each Fourier mode developed independently, and hence can be described by a driven harmonic oscillator, with frequency determined by the sound speed in

the fluid. Thus the fluid density underwent oscillations, giving time variations in temperature. These combine with a velocity effect which is $\pi/2$ out of phase and has its amplitude reduced by the sound speed.

After the Universe recombined, the radiation decoupled from the baryons and could travel freely towards us. At that point, the phases of the oscillations were frozen-in, and became projected on the sky as a harmonic series of peaks. The main peak is the mode that went through 1/4 of a period, reaching maximal compression. The even peaks are maximal under-densities, which are generally of smaller amplitude because the rebound has to fight against the baryon inertia. The troughs, which do not extend to zero power, are partially filled by the Doppler effect because they are at the velocity maxima.

The physical length scale associated with the peaks is the sound horizon at last scattering, which can be straightforwardly calculated. This length is projected onto the sky, leading to an angular scale that depends on the geometry of space, as well as the distance to last scattering. Hence the angular position of the peaks is a sensitive probe of the spatial curvature of the Universe (i.e., $\Omega_{\rm tot}$), with the peaks lying at higher ℓ in open universes and lower ℓ in closed geometry.

One additional effect arises from reionization at redshift $z_{\rm i}$. A fraction of photons (τ) will be isotropically scattered at $z < z_{\rm i}$, partially erasing the anisotropies at angular scales smaller than those subtended by the Hubble radius at $z_{\rm i}$. This corresponds typically to ℓ 's above about a few 10s, depending on the specific reionization model. The acoustic peaks are therefore reduced by a factor $e^{-2\tau}$ relative to the plateau.

These peaks were a clear theoretical prediction going back to about 1970 [29]. One can think of them as a snapshot of stochastic standing waves. Since the physics governing them is simple and their structure rich, then one can see how they encode extractable information about the cosmological parameters. Their empirical existence started to become clear around 1994 [30], and the emergence, over the following decade, of a coherent series of acoustic peaks and troughs is a triumph of modern cosmology. This picture has received further confirmation with the detection in the power spectrum of galaxies (at redshifts close to zero) of the imprint of these same acoustic oscillations in the baryon component [33–33].

25.4.3. The damping tail, $\ell \gtrsim 1000$:

The recombination process is not instantaneous, which imparts a thickness to the last scattering surface. This leads to a damping of the anisotropies at the highest ℓ 's, corresponding to scales smaller than that subtended by this thickness. One can also think of the photon-baryon fluid as having imperfect coupling, so that there is diffusion between the two components, and hence the amplitudes of the oscillations decrease with time. These effects lead to a damping of the C_{ℓ} 's, sometimes called Silk damping [34], which cuts off the anisotropies at multipoles above about 2000.

An extra effect at high ℓ 's comes from gravitational lensing, caused mainly by non-linear structures at low redshift. The C_{ℓ} 's are convolved with a smoothing function in a calculable way, partially flattening the peaks, generating a power-law tail at the highest multipoles, and complicating the polarization signal [35]. The effects of lensing on the CMB have recently been detected by correlating temperature gradients and small-scale filtered anisotropies from WMAP with lensing potentials traced using galaxies [36], as well as through the effect on the shape of the C_{ℓ} 's [37] and directly through the CMB 4-point function [38]. This is an example of a 'secondary effect,' i.e., the processing of anisotropies due to relatively nearby structures (see Sec. 25.7.2). Galaxies and clusters of galaxies give several such effects; all are expected to be of low amplitude and typically affect only the highest ℓ 's, but they carry additional cosmological information and will be increasingly important as experiments push to higher sensitivity and angular resolution [39].

25.5. Current Anisotropy Data

There has been a steady improvement in the quality of CMB data that has led to the development of the present-day cosmological model. Probably the most robust constraints currently available come from the combination of the WMAP 7-year data [40] with smaller scale results from the ACT [41] and SPT [42] experiments (together with constraints from other cosmological data-sets). We plot power spectrum estimates from these experiments, as well as ACBAR [43] and QUAD [44] in Fig. 25.2. Other recent experiments also give powerful constraints, which are quite consistent with what we describe below. There have been some comparisons among data-sets [45]. which indicate very good agreement, both in maps and in derived power spectra (up to systematic uncertainties in the overall calibration for some experiments). This makes it clear that systematic effects are largely under control. However, a fully self-consistent joint analysis of all the current data-sets has not been attempted, one of the reasons being that it would require a careful treatment of the overlapping sky coverage.

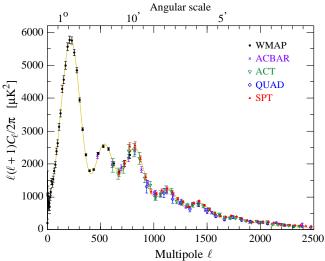

Figure 25.2: Band-power estimates from the WMAP, ACBAR, ACT, QUAD, and SPT experiments (omitting some band-powers which have larger error bars). Note that the widths of the ℓ -bands vary between experiments and have not been plotted. This figure represents only a selection of available experimental results, with some other data-sets being of similar quality. The multipole axis here is linear, so the Sachs-Wolfe plateau is hard to see. However, the acoustic peaks and damping region are very clearly observed, with no need for a theoretical curve to guide the eye; the curve plotted is a best-fit model from WMAP plus other CMB data. At high ℓ there is some departure from the model due to secondary anisotropies.

The band-powers shown in Fig. 25.2 are in very good agreement with a ' Λ CDM' model. As described earlier, several of the peaks and troughs are quite apparent. For details of how these estimates were arrived at, the strength of any correlations between band-powers and other information required to properly interpret them, the original papers should be consulted.

25.6. CMB Polarization

Since Thomson scattering of an anisotropic radiation field also generates linear polarization, the CMB is predicted to be polarized at the level of roughly 5% of the temperature anisotropies [46]. Polarization is a spin-2 field on the sky, and the algebra of the modes in ℓ -space is strongly analogous to spin-orbit coupling in quantum mechanics [47]. The linear polarization pattern can be decomposed in a number of ways, with two quantities required for each pixel in a map, often given as the Q and U Stokes parameters. However, the most intuitive and physical decomposition is a geometrical one, splitting the polarization pattern into a part that comes from a

divergence (often referred to as the 'E-mode') and a part with a curl (called the 'B-mode') [48]. More explicitly, the modes are defined in terms of second derivatives of the polarization amplitude, with the Hessian for the E-modes having principle axes in the same sense as the polarization, while the B-mode pattern can be thought of as a 45° rotation of the E-mode pattern. Globally one sees that the E-modes have $(-1)^{\ell}$ parity (like the spherical harmonics), while the B-modes have $(-1)^{\ell+1}$ parity.

The existence of this linear polarization allows for six different cross power spectra to be determined from data that measure the full temperature and polarization anisotropy information. Parity considerations make two of these zero, and we are left with four potential observables: $C_\ell^{\rm TT}$, $C_\ell^{\rm TE}$, $C_\ell^{\rm EE}$, and $C_\ell^{\rm BB}$. Because scalar perturbations have no handedness, the B-mode power spectrum can only be sourced by vectors or tensors. Moreover, since inflationary scalar perturbations give only E-modes, while tensors generate roughly equal amounts of E- and B-modes, then the determination of a non-zero B-mode signal is a way to measure the gravitational wave contribution (and thus potentially derive the energy scale of inflation), even if it is rather weak. However, one must first eliminate the foreground contributions and other systematic effects down to very low levels.

The oscillating photon-baryon fluid also results in a series of acoustic peaks in the polarization C_ℓ 's. The main 'EE' power spectrum has peaks that are out of phase with those in the 'TT' spectrum, because the polarization anisotropies are sourced by the fluid velocity. The 'TE' part of the polarization and temperature patterns comes from correlations between density and velocity perturbations on the last scattering surface, which can be both positive and negative, and is of larger amplitude than the EE signal. There is no polarization Sachs-Wolfe effect, and hence no large-angle plateau. However, scattering during a recent period of reionization can create a polarization 'bump' at large angular scales.

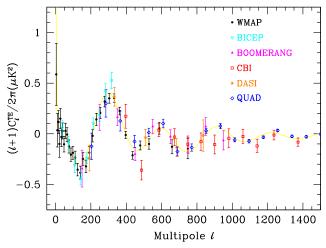

Figure 25.3: Cross power spectrum of the temperature anisotropies and E-mode polarization signal from WMAP, together with estimates from BICEP, BOOMERANG, CBI, DASI, and QUAD, several of which extend to higher ℓ . Note that the y-axis here is not multiplied by the additional ℓ , which helps to show both the large and small angular scale features.

Because the polarization anisotropies have only a fraction of the amplitude of the temperature anisotropies, they took longer to detect. The first measurement of a polarization signal came in 2002 from the DASI experiment [49], which provided a convincing detection, confirming the general paradigm, but of low enough significance that it lent little constraint to models. As well as the *E*-mode signal, DASI also made a statistical detection of the TE correlation.

The TE signal has now been mapped out quite accurately through data from WMAP [50], together with the BICEP [51], BOOMERANG [52], CBI [53], DASI [54], and QUAD [55] experiments, which are shown in Fig. 25.3. The anti-correlation

at $\ell \simeq 150$ and the peak at $\ell \simeq 300$ are now quite distinct. The measured shape of the cross-correlation power spectrum provides supporting evidence for the adiabatic nature of the perturbations, as well as directly constraining the thickness of the last scattering surface. Since the polarization anisotropies are generated in this scattering surface, the existence of correlations at angles above about a degree demonstrates that there were super-Hubble fluctuations at the recombination epoch. The sign of this correlation also confirms the adiabatic paradigm.

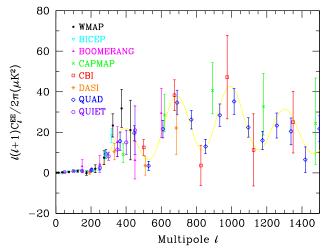

Figure 25.4: Power spectrum of *E*-mode polarization from several different experiments, plotted along with a theoretical model which fits WMAP plus other CMB data. Note that the widths of the bands have been suppressed for clarity, but that in some cases they are almost as wide as the features in the power spectrum.

Experimental band-powers for $C_\ell^{\rm EE}$ from WMAP plus BICEP [51], BOOMERANG [56], CAPMAP [57], CBI [53], DASI [54], QUAD [55] and QUIET [58] are shown in Fig. 25.4. Without the benefit of correlating with the temperature anisotropies (i.e., measuring $C_\ell^{\rm TE}$), the polarization anisotropies are very weak and challenging to measure. Nevertheless, there is a highly significant overall detection which is consistent with expectation. The data convincingly show the peak at $\ell \simeq 140$ (hard to see on this scale), the next peak at $\ell \simeq 400$ (corresponding to the first trough in $C_\ell^{\rm TT}$) and the generally oscillatory structure.

Several experiments have reported upper limits on C_ℓ^{BB} , but they are currently not very constraining. This situation should change as increasingly ambitious experiments report results.

The most distinctive novel from the polarization measurements is at the largest angular scales ($\ell < 10$) in C_ℓ^{TE} , where there is an excess signal compared to that expected from the temperature power spectrum alone. This is precisely the signal anticipated from an early period of reionization, arising from Doppler shifts during the partial scattering at $z < z_i$. The effect is also confirmed in the WMAP C_ℓ^{EE} results at $\ell = 2-7$ [50]. The amplitude of the signal indicates that the first stars, presumably the source of the ionizing radiation, formed around $z \simeq 10$ (although the uncertainty is still quite large). Since this corresponds to scattering optical depth $\tau \simeq 0.1$, then roughly 10% of CMB photons were re-scattered at the reionization epoch, with the other 90% last scattering at $z \simeq 1100$.

25.7. Complications

There are a number of issues which complicate the interpretation of CMB anisotropy data (and are considered to be *signal* by many astrophysicists), some of which we sketch out below.

25.7.1. Foregrounds:

The microwave sky contains significant emission from our Galaxy and from extra-galactic sources [59,60]. Fortunately, the frequency dependence of these various sources is in general substantially different from that of the CMB anisotropy signals. The combination of Galactic synchrotron, bremsstrahlung, and dust emission reaches a minimum at a wavelength of roughly 3 mm (or about 100 GHz). As one moves to greater angular resolution, the minimum moves to slightly higher frequencies, but becomes more sensitive to unresolved (point-like) sources.

At frequencies around 100 GHz, and for portions of the sky away from the Galactic Plane, the foregrounds are typically 1 to 10% of the CMB anisotropies. By making observations at multiple frequencies, it is relatively straightforward to separate the various components and determine the CMB signal to the few per cent level. For greater sensitivity, it is necessary to use the spatial information and statistical properties of the foregrounds to separate them from the CMB.

The foregrounds for CMB polarization follow a similar pattern, but are less well studied, and are intrinsically more complicated. WMAP has shown that the polarized foregrounds dominate at large angular scales, and that they must be well characterized in order to be discriminated [60]. Whether it is possible to achieve sufficient separation to detect *B*-mode CMB polarization is still an open question. However, for the time being, foreground contamination is not a fundamental limit for CMB experiments.

25.7.2. Secondary Anisotropies:

With increasingly precise measurements of the primary anisotropies, there is growing theoretical and experimental interest in 'secondary anisotropies,' pushing experiments to higher angular resolution and sensitivity. These secondary effects arise from the processing of the CMB due to ionization history and the evolution of structure, including gravitational lensing and patchy reionization effects [61]. Additional information can thus be extracted about the Universe at $z\ll 1000$. This tends to be most effectively done through correlating CMB maps with other cosmological probes of structure. Secondary signals are also typically non-Gaussian, unlike the primary CMB anisotropies.

A secondary signal of great current interest is the Sunyaev-Zeldovich (SZ) effect [62], which is Compton scattering ($\gamma e \to \gamma' e'$) of the CMB photons by hot electron gas. This creates spectral distortions by transferring energy from the electrons to the photons. It is particularly important for clusters of galaxies, through which one observes a partially Comptonized spectrum, resulting in a decrement at radio wavelengths and an increment in the submillimeter.

The imprint on the CMB sky is of the form $\Delta T/T = y f(x)$, with the y-parameter being the integral of Thomson optical depth times $kT_{\rm e}/m_{\rm e}c^2$ through the cluster, and f(x) describing the frequency dependence. This is simply $x \coth(x/2) - 4$ for a non-relativistic gas (the electron temperature in a cluster is typically a few keV), where the dimensionless frequency $x \equiv h\nu/kT_{\gamma}$. As well as this 'thermal' SZ effect, there is also a smaller 'kinetic' effect due to the bulk motion of the cluster gas, giving $\Delta T/T \sim \tau(v/c)$, with either sign, but having the same spectrum as the primary CMB anisotropies.

A significant advantage in finding galaxy clusters this way is that the SZ effect is largely independent of redshift, so in principle clusters can be found to arbitrarily large distances. The SZ effect can be used to find and study individual clusters, and to obtain estimates of the Hubble constant. There is also the potential to constrain the equation of state of the dark energy through counts of detected clusters as a function of redshift [63]. Many experiments are currently in operation which will probe clusters in this way. The promise of the method has been realized through detections of clusters purely through the SZ effect, by SPT [64], ACT [65] and Planck [66].

${\bf 25.7.3.} \quad Higher-order\ Statistics:$

Although most of the CMB anisotropy information is contained in the power spectra, there will also be weak signals present in higher-order statistics. These can measure any primordial non-Gaussianity in the perturbations, as well as non-linear growth of the fluctuations on small scales and other secondary effects (plus residual foreground contamination of course). Although there are an infinite variety of ways in which the CMB could be non-Gaussian [17], there is a

generic form to consider for the initial conditions, where a quadratic contribution to the curvature perturbations is parameterized through a dimensionless number $f_{\rm NL}$. This weakly non-linear component can be constrained using measurements of the bispectrum or Minkowski functionals, for example. The constraints depend on the shape of the triangles in harmonic space, and it has become common to distinguish the 'local' or 'squeezed' configuration (in which one side is much smaller than the other two) from the 'equilateral' configuration. The results from the WMAP team are $-10 < f_{\rm NL} < 74$ (95% confidence region), for the local mode and $-214 < f_{\rm NL} < 266$ for the equilateral mode [40]. Different estimators used by other authors give results of similar magnitude [67].

The level of $f_{\rm NL}$ expected is small, so that a detection of $f_{\rm NL} \gtrsim 10$ would rule out all single field, slow-roll inflationary models. However, with the capabilities of Planck and other future experiments, it seems that a measurement of primordial non-Gaussianity may be feasible for a wide class of models, and therefore much effort is expected to be devoted to predictions and measurements in the coming years.

25.8. Constraints on Cosmologies

The most striking outcome of the newer experimental results is that the standard cosmological paradigm is in very good shape. A large amount of high precision data on the power spectrum is adequately fit with fewer than 10 free parameters. The framework is that of FRW models, which have nearly flat geometry, containing dark matter and dark energy, and with adiabatic perturbations having close to scale invariant initial conditions.

Within this basic picture, the values of the cosmological parameters can be constrained. Of course, much more stringent bounds can be placed on models which cover a restricted parameter space, e.g., assuming that $\Omega_{\rm tot}=1,\ n=1$ or r=0. More generally, the constraints depend upon the adopted prior probability distributions, even if they are implicit, for example by restricting the parameter freedom or their ranges (particularly where likelihoods peak near the boundaries), or by using different choices of other data in combination with the CMB. When the data become even more precise, these considerations will be less important, but for now we caution that restrictions on model space and choice of priors need to be kept in mind when adopting specific parameter values and uncertainties.

There are some combinations of parameters that fit the CMB anisotropies almost equivalently. For example, there is a nearly exact geometric degeneracy, where any combination of $\Omega_{\rm m}$ and Ω_{Λ} that gives the same angular diameter distance to last scattering will give nearly identical C_ℓ 's. There are also other less exact degeneracies among the parameters. Such degeneracies can be broken when using the CMB results in combination with other cosmological data-sets. Particularly useful are complementary constraints from galaxy clustering, the abundance of galaxy clusters, baryon acoustic oscillations, weak gravitational lensing measurements, Type Ia supernova distances, and the distribution of Lyman α forest clouds. For an overview of some of these other cosmological constraints, see The Cosmological Parameters—Sec. 23 of this Review.

The 7-year WMAP data alone, within the context of a six parameter family of models (which fixes $\Omega_{\rm tot}=1$ and r=0), yield the following results [50]: $A=(2.43\pm0.11)\times10^{-9};~n=0.967\pm0.014;~h=0.704\pm0.025;~\Omega_{\rm b}h^2=0.0225\pm0.0006;~\Omega_{\rm m}h^2=0.134\pm0.006;~{\rm and}~\tau=0.088\pm0.015.$ There has been little substantive change compared with earlier results, although it is now possible to obtain this 6-parameter set without using additional cosmological data-sets. Compared with the earliest WMAP results, the better measurement of the third acoustic peak, together with improved understanding of calibration issues has led to tighter error bars on dark matter density and overall normalization. The evidence for non-zero reionization optical depth is now very compelling, while the evidence for n<1 is still only at the roughly 3σ level.

Other combinations of data, e.g., including additional CMB measurements, or using other cosmological data-sets, lead to consistent results to those given above, sometimes with smaller error bars, and with the precise values depending on data selection [33,55,68,42] (see Sec. 23 of this Review). Note that for h, the CMB data alone provide only a very weak constraint, unless spatial flatness or some other cosmological data are used. For $\Omega_{\rm b}h^2$, the precise value depends

sensitively on how much freedom is allowed in the shape of the primordial power spectrum (see Sec. 22 of this Review). The addition of other data-sets also allows for constraints to be placed on further parameters.

For $\Omega_{\rm tot}$, perhaps the best WMAP constraint is 1.002 ± 0.006 [40], from the combination with Hubble constant [22] and baryon acoustic oscillation [33] constraints (and setting w=-1). The 95% confidence upper limit on r is 0.36 using WMAP alone [50], tightening to r<0.17 with the addition of other data [42]. This limit depends on how the slope n is restricted and whether $dn/d\ln k \neq 0$ is allowed. Nevertheless, it is clear that $\lambda\phi^4$ (sometimes called self-coupled) inflation is disfavored by the data, while the $m^2\phi^2$ (sometimes called mass term) inflationary model is still allowed [40]. Gravitational wave constraints coming directly from B-mode limits are at the level of r<0.73 [51].

There are also constraints on parameters over and above the basic eight that we have described, usually requiring extra cosmological data to break degeneracies. For example, the addition of the dark energy equation of state w adds the partial degeneracy of being able to fit a ridge in (w,h) space, extending to low values of both parameters. This degeneracy is broken when the CMB is used in combination with independent H_0 limits, or other data. For example, WMAP plus baryon acoustic oscillation and supernova data [70] yields $w=-1.00\pm0.06$, even without assuming flatness.

For the optical depth τ , the best-fit corresponds to a reionization redshift centered on 10.5 in the best-fit cosmology, and assuming instantaneous reionization. This redshift appears to be higher that that suggested from studies of absorption in high-z quasar spectra [71], perhaps indicating that the process of reionization was complex. The important constraint provided by CMB polarization, in combination with astrophysical measurements, allows us to investigate how the first stars formed and brought about the end of the cosmic dark ages.

25.9. Particle Physics Constraints

CMB data are beginning to put limits on parameters which are directly relevant for particle physics models. For example, there is a limit on the neutrino contribution $\Omega_{\nu}h^2 < 0.0062$ (95% confidence) from a combination of WMAP and other data [18]. This directly implies a limit on neutrino mass, $\sum m_{\nu} < 0.58\,\mathrm{eV}$, assuming the usual number density of fermions which decoupled when they were relativistic. Some tighter constraints can be derived using the CMB in combination with other data-sets [72].

The current suite of data suggests that n<1, with a best-fitting value about 0.03 below unity. If borne out, this would be quite constraining for inflationary models. Moreover, it gives a real target for B-mode searches, since the value of r in simple models may be in the range of detectability, e.g., $r\sim0.12$ for $m^2\phi^2$ inflation if $n\simeq0.97$. In addition, a combination of the WMAP data with other data-sets constrains the running of the spectral index, although at the moment there is no evidence for $dn/d\ln k \neq 0$ [40].

One other possible hint of new physics lies in the fact that the quadrupole seems anomalously low and also appears remarkably well aligned with the octupole. Additionally there is some weak evidence for a large scale modulation of the smaller-scale power [73]. These effects might be expected in a universe which has a large-scale cut-off, or anisotropy in the initial power spectrum, or is topologically non-trivial. However, cosmic variance, a posteriori statistics, possible foregrounds, apparent correlations between modes (as mentioned in Sec. 25.2), etc., limit the significance of these anomalies, and for now the general view is that such features are not unreasonably unlikely within the Λ CDM paradigm [19].

It is also possible to put limits on other pieces of physics [74], for example the neutrino chemical potentials, contribution of warm dark matter, decaying particles, parity violation, time variation of the fine-structure constant, topological defects, or physics beyond general relativity. Further particle physics constraints will follow as the anisotropy measurements increase in precision.

Careful measurement of the CMB power spectra and non-Gaussianity can in principle put constraints on physics at the highest energies, including ideas of string theory, extra dimensions, colliding branes, etc. At the moment any calculation of predictions appears to be far from definitive. However, there is a great deal of activity on

implications of string theory for the early Universe, and hence a very real chance that there might be observational implications for specific scenarios.

25.10. Fundamental Lessons

More important than the precise values of parameters is what we have learned about the general features which describe our observable Universe. Beyond the basic hot Big Bang picture, the CMB has taught us that:

- The Universe recombined at $z\simeq 1100$ and started to become ionized again at $z\simeq 10$.
- The geometry of the Universe is close to flat.
- Both dark matter and dark energy are required.
- Gravitational instability is sufficient to grow all of the observed large structures in the Universe.
- Topological defects were not important for structure formation.
- There are 'synchronized' super-Hubble modes generated in the early Universe.
- The initial perturbations were predominantly adiabatic in nature.
- The perturbations had close to Gaussian (i.e., maximally random) initial conditions.

It is very tempting to make an analogy between the status of the cosmological 'Standard Model' and that of particle physics (see earlier Sections of this *Review*). In cosmology there are about 10 free parameters, each of which is becoming well determined, and with a great deal of consistency between different measurements. However, none of these parameters can be calculated from a fundamental theory, and so hints of the bigger picture, 'physics beyond the Standard Model,' are being searched for with ever more ambitious experiments.

Despite this analogy, there are some basic differences. For one thing, many of the cosmological parameters change with cosmic epoch, and so the measured values are simply the ones determined today, and hence they are not 'constants,' like particle masses for example (although they are deterministic, so that if one knows their values at one epoch, they can be calculated at another). Moreover, the parameter set is not as well defined as it is in the particle physics Standard Model; different researchers will not necessarily agree on which parameters should be considered as free, and the set can be extended as the quality of the data improves. In addition, parameters like τ , which come from astrophysics, are in principle calculable from known physical processes. On top of all this, other parameters might be 'stochastic' in that they may be fixed only in our observable patch of the Universe or among certain vacuum states in the 'Landscape' [76].

In a more general sense, the cosmological 'Standard Model' is much further from the underlying 'fundamental theory,' which will ultimately provide the values of the parameters from first principles. Nevertheless, any genuinely complete 'theory of everything' must include an explanation for the values of these cosmological parameters as well as the parameters of the Standard Model of particle physics.

25.11. Future Directions

Given the significant progress in measuring the CMB sky, which has been instrumental in tying down the cosmological model, what can we anticipate for the future? There will be a steady improvement in the precision and confidence with which we can determine the appropriate cosmological parameters. Ground-based experiments operating at smaller angular scales will continue to place tighter constraints on the damping tail. New polarization experiments will push down the limits on primordial B-modes. The third generation CMB satellite mission, Planck, was launched successfully in May 2009, and has already led to many papers on foregrounds and secondary anisotropies [9]. Cosmological results from the primary CMB anisotropies are expected from Planck in early 2013 and are keenly anticipated.

Despite the increasing improvement in the results, the addition of the latest experiments has not significantly changed the established cosmological model. It is, therefore, appropriate to ask: what should we expect to come from *Planck* and from other future experiments? *Planck* certainly has the advantage of high sensitivity and a full-sky survey. A precise measurement of the third acoustic peak provides

a good determination of the matter density; this can only be done by measurements which are accurate relative to the first two peaks (which themselves constrain the curvature and the baryon density). A detailed measurement of the damping tail region will also significantly improve the determination of n and any running of the slope. Planck should be capable of measuring $C_\ell^{\rm EE}$ quite well, providing both a strong check on the cosmological Standard Model and extra constraints that will improve parameter estimation.

A set of cosmological parameters is now known to roughly 10% accuracy, and that may seem sufficient for many people. However, we should certainly demand more of measurements which describe the entire observable Universe! Hence a lot of activity in the coming years will continue to focus on determining those parameters with increasing precision. This necessarily includes testing for consistency among different predictions of the cosmological Standard Model, and searching for signals which might require additional physics.

A second area of focus will be the smaller scale anisotropies and 'secondary effects.' There is a great deal of information about structure formation at $z\ll 1000$ encoded in the CMB sky. This may involve higher-order statistics as well as spectral signatures, with many new experiments targeting the galaxy cluster SZ effect. Such investigations can also provide constraints on the dark energy equation of state, for example. Planck, as well as new telescopes aimed at the highest ℓ 's, should be able to make a lot of progress in this arena.

A third direction is increasingly sensitive searches for specific signatures of physics at the highest energies. The most promising of these may be the primordial gravitational wave signals in $C_\ell^{\rm BB}$, which could be a probe of the $\sim 10^{16}\,\rm GeV$ energy range. As well as *Planck*, there are several ground- and balloon-based experiments underway which are designed to search for the polarization *B*-modes. Whether the amplitude of the effect coming from inflation will be detectable is unclear, but the prize makes the effort worthwhile, and the indications that $n\simeq 0.95$ give some genuine optimism that r (the tensor to scalar ratio) may be of order 0.1, and hence within reach soon.

Anisotropies in the CMB have proven to be the premier probe of cosmology and the early Universe. Theoretically the CMB involves well understood physics in the linear regime, and is under very good calculational control. A substantial and improving set of observational data now exists. Systematics appear to be under control and not a limiting factor. And so for the next few years we can expect an increasing amount of cosmological information to be gleaned from CMB anisotropies, with the prospect also of some genuine surprises.

26. COSMIC RAYS

Revised August 2011 by J.J. Beatty (Ohio State Univ.) and J. Matthews (Louisiana State Univ. and Southern Univ.); revised August 2009 by T.K. Gaisser and T. Stanev (Bartol Research Inst., Univ. of Delaware).

26.1. Primary spectra

The cosmic radiation incident at the top of the terrestrial atmosphere includes all stable charged particles and nuclei with lifetimes of order 10⁶ years or longer. Technically, "primary" cosmic rays are those particles accelerated at astrophysical sources and "secondaries" are those particles produced in interaction of the primaries with interstellar gas. Thus electrons, protons and helium, as well as carbon, oxygen, iron, and other nuclei synthesized in stars, are primaries. Nuclei such as lithium, beryllium, and boron (which are not abundant end-products of stellar nucleosynthesis) are secondaries. Antiprotons and positrons are also in large part secondary. Whether a small fraction of these particles may be primary is a question of current interest.

Apart from particles associated with solar flares, the cosmic radiation comes from outside the solar system. The incoming charged particles are "modulated" by the solar wind, the expanding magnetized plasma generated by the Sun, which decelerates and partially excludes the lower energy galactic cosmic rays from the inner solar system. There is a significant anticorrelation between solar activity (which has an alternating eleven-year cycle) and the intensity of the cosmic rays with energies below about 10 GeV. In addition, the lower-energy cosmic rays are affected by the geomagnetic field, which they must penetrate to reach the top of the atmosphere. Thus the intensity of any component of the cosmic radiation in the GeV range depends both on the location and time.

There are four different ways to describe the spectra of the components of the cosmic radiation: (1) By particles per unit rigidity. Propagation (and probably also acceleration) through cosmic magnetic fields depends on gyroradius or magnetic rigidity, R, which is gyroradius multiplied by the magnetic field strength:

$$R = \frac{pc}{Ze} = r_L B \ . \tag{26.1}$$

(2) By particles per energy-per-nucleon. Fragmentation of nuclei propagating through the interstellar gas depends on energy per nucleon, since that quantity is approximately conserved when a nucleus breaks up on interaction with the gas. (3) By nucleons per energy-per-nucleon. Production of secondary cosmic rays in the atmosphere depends on the intensity of nucleons per energy-per-nucleon, approximately independently of whether the incident nucleons are free protons or bound in nuclei. (4) By particles per energy-per-nucleus. Air shower experiments that use the atmosphere as a calorimeter generally measure a quantity that is related to total energy per particle.

The units of differential intensity I are $[m^{-2}s^{-1}sr^{-1}\mathcal{E}^{-1}]$, where \mathcal{E} represents the units of one of the four variables listed above.

The intensity of primary nucleons in the energy range from several GeV to somewhat beyond 100 TeV is given approximately by

$$I_N(E) \approx 1.8 \times 10^4 \; (E/1 \; {\rm GeV})^{-\alpha} \; \frac{\rm nucleons}{\rm m^2 \; s \; sr \; GeV} \; ,$$
 (26.2)

where E is the energy-per-nucleon (including rest mass energy) and $\alpha \ (\equiv \gamma+1)=2.7$ is the differential spectral index of the cosmic ray flux and γ is the integral spectral index. About 79% of the primary nucleons are free protons and about 70% of the rest are nucleons bound in helium nuclei. The fractions of the primary nuclei are nearly constant over this energy range (possibly with small but interesting variations). Fractions of both primary and secondary incident nuclei are listed in Table 26.1. Figure 26.1 shows the major components for energies greater than 2 GeV/nucleon.

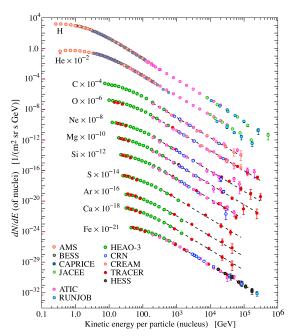

Figure 26.1: Fluxes of nuclei of the primary cosmic radiation in particles per energy-per-nucleus are plotted vs energy-per-nucleus using data from Refs. [1–12]. The figure was created by P. Boyle and D. Muller.

The composition and energy spectra of nuclei are typically interpreted in the context of propagation models, in which the sources of the primary cosmic radiation are located within the galaxy [16]. The ratio of secondary to primary nuclei is observed to decrease with increasing energy, a fact interpreted to mean that the lifetime of cosmic rays in the galaxy decreases with energy. Measurements of radioactive "clock" isotopes in the low energy cosmic radiation are consistent with a lifetime in the galaxy of about 15 Myr.

Table 26.1: Relative abundances F of cosmic-ray nuclei at 10.6 GeV/nucleon normalized to oxygen ($\equiv 1$) [6]. The oxygen flux at kinetic energy of 10.6 GeV/nucleon is $3.26 \times 10^{-2} \text{ (m}^2 \text{ s sr GeV/nucleon)}^{-1}$. Abundances of hydrogen and helium are from Refs. [2,3]. Note that one can not use these values to extend the cosmic ray flux to high energy because the power law indicies for each element may differ slightly.

| \overline{Z} | Element | F | \overline{Z} | Element | F |
|----------------|---------|------|----------------|------------------------|------|
| 1 | Н | 540 | 13–14 | Al-Si | 0.19 |
| 2 | He | 26 | 15 - 16 | P-S | 0.03 |
| 3-5 | Li-B | 0.40 | 17 - 18 | Cl-Ar | 0.01 |
| 6-8 | C-O | 2.20 | 19 - 20 | K-Ca | 0.02 |
| 9 - 10 | F-Ne | 0.30 | 21 - 25 | $\operatorname{Sc-Mn}$ | 0.05 |
| 11-12 | Na-Mg | 0.22 | 26-28 | Fe-Ni | 0.12 |

Cosmic rays are nearly isotropic at most energies due to diffusive propagation in the galactic magnetic field. Milagro [13], IceCube [14], and The Tibet-III air shower array [15] have observed anisotropy at the level of about 10^{-3} for cosmic rays with energy of a few TeV, possibly due to nearby sources.

The spectrum of electrons and positrons incident at the top of the atmosphere is expected to steepen by one power of E at an energy of ~ 5 GeV because of the strong synchrotron energy loss in the galactic magnetic fields. The ATIC experiment [21] measured an excess of electrons above 100 GeV followed by a steepening above 1,000 GeV. The Fermi/LAT γ -ray observatory confirmed the relatively

flat electron spectrum [23] without confirming the peak of the ATIC excess at ${\sim}800$ GeV.

The PAMELA satellite experiment [24] measured the positron to electron ratio to increase above 10 GeV instead of the expected decrease [25] at higher energy. The structure in the electron spectrum as well as the increase in the positron fraction could be related to contributions from individual nearby sources emerging above a background suppressed at high energy by synchrotron losses [26]. The low positron to electron ratio below 10 GeV is due to the new solar magnetic field polarity after the year 2001.

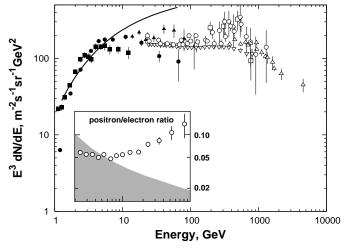

Figure 26.2: Differential spectrum of electrons plus positrons multiplied by E^3 (data from [17–23]). The line shows the proton spectrum multiplied by 0.01. The inset shows the positron to electron ratio measured by PAMELA [24] compared to the expected decrease [25].

The ratio of antiprotons to protons is $\sim 2 \times 10^{-4}$ [27] at around 10–20 GeV, and there is clear evidence [28] for the kinematic suppression at lower energy that is the signature of secondary antiprotons. The \overline{p}/p ratio also shows a strong dependence on the phase and polarity of the solar cycle [29] in the opposite sense to that of the positron fraction. There is at this time no evidence for a significant primary component of antiprotons. No antihelium or antideuteron has been found in the cosmic radiation. The best measured upper limit on the ratio antihelium/helium is currently approximately 1×10^{-7} [30] The upper limit on the flux of antideuterons around 1 GeV/nucleon is approximately 2×10^{-4} (m² s sr GeV/nucleon)⁻¹ [31].

26.2. Cosmic rays in the atmosphere

Figure 26.3 shows the vertical fluxes of the major cosmic ray components in the atmosphere in the energy region where the particles are most numerous (except for electrons, which are most numerous near their critical energy, which is about 81 MeV in air). Except for protons and electrons near the top of the atmosphere, all particles are produced in interactions of the primary cosmic rays in the air. Muons and neutrinos are products of the decay chain of charged mesons, while electrons and photons originate in decays of neutral mesons.

Most measurements are made at ground level or near the top of the atmosphere, but there are also measurements of muons and electrons from airplanes and balloons. Fig. 26.3 includes recent measurements of negative muons [32–36]. Since $\mu^+(\mu^-)$ are produced in association with $\nu_{\mu}(\overline{\nu}_{\mu})$, the measurement of muons near the maximum of the intensity curve for the parent pions serves to calibrate the atmospheric ν_{μ} beam [37]. Because muons typically lose almost 2 GeV in passing through the atmosphere, the comparison near the production altitude is important for the sub-GeV range of $\nu_{\mu}(\overline{\nu}_{\mu})$ energies.

The flux of cosmic rays through the atmosphere is described by a set of coupled cascade equations with boundary conditions at the

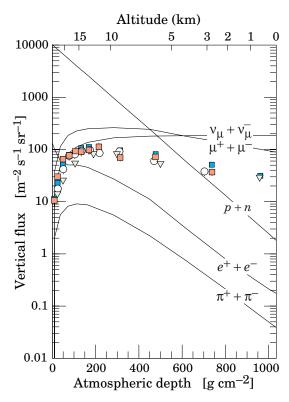

Figure 26.3: Vertical fluxes of cosmic rays in the atmosphere with E>1 GeV estimated from the nucleon flux of Eq. (26.2). The points show measurements of negative muons with $E_{\mu}>1$ GeV [32–36].

top of the atmosphere to match the primary spectrum. Numerical or Monte Carlo calculations are needed to account accurately for decay and energy-loss processes, and for the energy-dependences of the cross sections and of the primary spectral index γ . Approximate analytic solutions are, however, useful in limited regions of energy [38,39]. For example, the vertical intensity of charged pions with energy $E_\pi \ll \epsilon_\pi = 115~{\rm GeV}$ is

$$I_{\pi}(E_{\pi}, X) \approx \frac{Z_{N\pi}}{\lambda_N} I_N(E_{\pi}, 0) e^{-X/\Lambda} \frac{X E_{\pi}}{\epsilon_{\pi}},$$
 (26.3)

where Λ is the characteristic length for exponential attenuation of the parent nucleon flux in the atmosphere. This expression has a maximum at $X=\Lambda\approx 121\pm 4~{\rm g~cm^{-2}}$ [40], which corresponds to an altitude of 15 kilometers. The quantity $Z_{N\pi}$ is the spectrum-weighted moment of the inclusive distribution of charged pions in interactions of nucleons with nuclei of the atmosphere. The intensity of low-energy pions is much less than that of nucleons because $Z_{N\pi}\approx 0.079$ is small and because most pions with energy much less than the critical energy ϵ_{π} decay rather than interact.

26.3. Cosmic rays at the surface

26.3.1. Muons: Muons are the most numerous charged particles at sea level (see Fig. 26.3). Most muons are produced high in the atmosphere (typically 15 km) and lose about 2 GeV to ionization before reaching the ground. Their energy and angular distribution reflect a convolution of the production spectrum, energy loss in the atmosphere, and decay. For example, 2.4 GeV muons have a decay length of 15 km, which is reduced to 8.7 km by energy loss. The mean energy of muons at the ground is ≈ 4 GeV. The energy spectrum is almost flat below 1 GeV, steepens gradually to reflect the primary spectrum in the 10–100 GeV range, and steepens further at higher energies because pions with $E_\pi > \epsilon_\pi$ tend to interact in the atmosphere before they decay. Asymptotically ($E_\mu \gg 1$ TeV), the energy spectrum of atmospheric muons is one power steeper than the primary spectrum.

The integral intensity of vertical muons above 1 GeV/c at sea level is $\approx 70~{\rm m}^{-2}{\rm s}^{-1}{\rm sr}^{-1}$ [41,42], with recent measurements [43–45] favoring a lower normalization by 10-15%. Experimentalists are familiar with this number in the form $I\approx 1~{\rm cm}^{-2}~{\rm min}^{-1}$ for horizontal detectors. The overall angular distribution of muons at the ground is $\propto \cos^2\theta$, which is characteristic of muons with $E_{\mu}\sim 3~{\rm GeV}$. At lower energy the angular distribution becomes increasingly steep, while at higher energy it flattens, approaching a $\sec\theta$ distribution for $E_{\mu}\gg\epsilon_{\pi}$ and $\theta<70^{\circ}$.

Figure 26.4 shows the muon energy spectrum at sea level for two angles. At large angles low energy muons decay before reaching the surface and high energy pions decay before they interact, thus the average muon energy increases. An approximate extrapolation formula valid when muon decay is negligible $(E_{\mu} > 100/\cos\theta~{\rm GeV})$ and the curvature of the Earth can be neglected $(\theta < 70^{\circ})$ is

$$\frac{dN_{\mu}}{dE_{\mu}d\Omega} \approx \frac{0.14 E_{\mu}^{-2.7}}{\text{cm}^2 \text{ s sr GeV}} \times \left\{ \frac{1}{1 + \frac{1.1E_{\mu}\cos\theta}{115 \text{ GeV}}} + \frac{0.054}{1 + \frac{1.1E_{\mu}\cos\theta}{850 \text{ GeV}}} \right\} , \quad (26.4)$$

where the two terms give the contribution of pions and charged kaons. Eq. (26.4) neglects a small contribution from charm and heavier flavors which is negligible except at very high energy [50].

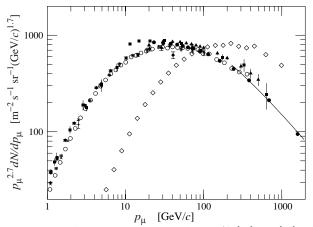

Figure 26.4: Spectrum of muons at $\theta = 0^{\circ}$ (\blacklozenge [41], \blacksquare [46], \checkmark [47], \blacktriangle [48], \times , + [43], \circ [44], and \bullet [45] and $\theta = 75^{\circ} \diamond$ [49]). The line plots the result from Eq. (26.4) for vertical showers.

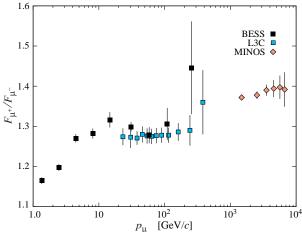

Figure 26.5: Muon charge ratio as a function of the muon momentum from Refs. [44,45,51].

The muon charge ratio reflects the excess of π^+ over π^- and K^+ over K^- in the forward fragmentation region of proton initiated interactions together with the fact that there are more protons than neutrons in the primary spectrum. The increase with energy of μ^+/μ^- shown in Fig. 26.5 reflects the increasing importance of kaons in the TeV range [51] and indicates a significant contribution of associated production by cosmic-ray protons $(p \to \Lambda + K^+)$. The same process is even more important for atmospheric neutrinos at high energy.

26.3.2. Electromagnetic component: At the ground, this component consists of electrons, positrons, and photons primarily from cascades initiated by decay of neutral and charged mesons. Muon decay is the dominant source of low-energy electrons at sea level. Decay of neutral pions is more important at high altitude or when the energy threshold is high. Knock-on electrons also make a small contribution at low energy [52]. The integral vertical intensity of electrons plus positrons is very approximately 30, 6, and $0.2 \text{ m}^{-2}\text{s}^{-1}\text{sr}^{-1}$ above 10, 100, and 1000 MeV respectively [42,53], but the exact numbers depend sensitively on altitude, and the angular dependence is complex because of the different altitude dependence of the different sources of electrons [52–54]. The ratio of photons to electrons plus positrons is approximately 1.3 above 1 GeV and 1.7 below the critical energy [54].

26.3.3. Protons: Nucleons above 1 GeV/c at ground level are degraded remnants of the primary cosmic radiation. The intensity is approximately $I_N(E,0) \times \exp(-X/\cos\theta\Lambda)$ for $\theta < 70^\circ$. At sea level, about 1/3 of the nucleons in the vertical direction are neutrons (up from $\approx 10\%$ at the top of the atmosphere as the n/p ratio approaches equilibrium). The integral intensity of vertical protons above 1 GeV/c at sea level is $\approx 0.9~\text{m}^{-2}\text{s}^{-1}\text{sr}^{-1}$ [42,55].

26.4. Cosmic rays underground

Only muons and neutrinos penetrate to significant depths underground. The muons produce tertiary fluxes of photons, electrons, and hadrons.

26.4.1. *Muons*: As discussed in Section 30.6 of this *Review*, muons lose energy by ionization and by radiative processes: bremsstrahlung, direct production of e^+e^- pairs, and photonuclear interactions. The total muon energy loss may be expressed as a function of the amount of matter traversed as

$$-\frac{dE_{\mu}}{dX} = a + b E_{\mu} , \qquad (26.5)$$

where a is the ionization loss and b is the fractional energy loss by the three radiation processes. Both are slowly varying functions of energy. The quantity $\epsilon \equiv a/b$ (≈ 500 GeV in standard rock) defines a critical energy below which continuous ionization loss is more important than radiative losses. Table 26.2 shows a and b values for standard rock, and b for ice, as a function of muon energy. The second column of Table 26.2 shows the muon range in standard rock ($A=22, Z=11, \rho=2.65 \text{ g cm}^{-3}$). These parameters are quite sensitive to the chemical composition of the rock, which must be evaluated for each location.

Table 26.2: Average muon range R and energy loss parameters a and b calculated for standard rock [56] and the total energy loss parameter b for ice. Range is given in km-water-equivalent, or 10^5 g cm⁻².

| | | ${\rm ^{a}~MeVg^{-1}cm^{2}}$ | | | | | $\sum b(ice)$ |
|-------|------|------------------------------|------|------|------|------|---------------|
| 10 | 0.05 | 2.17 | 0.70 | 0.70 | 0.50 | 1.90 | 1.66 |
| 100 | 0.41 | 2.44 | 1.10 | 1.53 | 0.41 | 3.04 | 2.51 |
| 1000 | 2.45 | 2.68 | 1.44 | 2.07 | 0.41 | 3.92 | 3.17 |
| 10000 | 6.09 | 2.93 | 1.62 | 2.27 | 0.46 | 4.35 | 3.78 |

The intensity of muons underground can be estimated from the muon intensity in the atmosphere and their rate of energy loss. To the extent that the mild energy dependence of a and b can be neglected, Eq. (26.5) can be integrated to provide the following relation between the energy $E_{\mu,0}$ of a muon at production in the atmosphere and its average energy E_{μ} after traversing a thickness X of rock (or ice or water):

$$E_{\mu,0} = (E_{\mu} + \epsilon) e^{bX} - \epsilon . \qquad (26.6)$$

Especially at high energy, however, fluctuations are important and an accurate calculation requires a simulation that accounts for stochastic energy-loss processes [57].

There are two depth regimes for which Eq. (26.6) can be simplified. For $X \ll b^{-1} \approx 2.5$ km water equivalent, $E_{\mu,0} \approx E_{\mu}(X) + aX$, while for $X \gg b^{-1}$ $E_{\mu,0} \approx (\epsilon + E_{\mu}(X)) \exp(bX)$. Thus at shallow depths the differential muon energy spectrum is approximately constant for $E_{\mu} < aX$ and steepens to reflect the surface muon spectrum for $E_{\mu} > aX$, whereas for X > 2.5 km.w.e. the differential spectrum underground is again constant for small muon energies but steepens to reflect the surface muon spectrum for $E_{\mu} > \epsilon \approx 0.5$ TeV. In the deep regime the shape is independent of depth although the intensity decreases exponentially with depth. In general the muon spectrum at slant depth X is

$$\frac{dN_{\mu}(X)}{dE_{\mu}} = \frac{dN_{\mu}}{dE_{\mu,0}} \frac{dE_{\mu,0}}{dE_{\mu}} = \frac{dN_{\mu}}{dE_{\mu,0}} e^{bX} , \qquad (26.7)$$

where $E_{\mu,0}$ is the solution of Eq. (26.6) in the approximation neglecting fluctuations.

Fig. 26.6 shows the vertical muon intensity versus depth. In constructing this "depth-intensity curve," each group has taken account of the angular distribution of the muons in the atmosphere, the map of the overburden at each detector, and the properties of the local medium in connecting measurements at various slant depths and zenith angles to the vertical intensity. Use of data from a range of angles allows a fixed detector to cover a wide range of depths. The flat portion of the curve is due to muons produced locally by charged-current interactions of ν_{μ} . The inset shows the vertical intensity curve for water and ice published in Refs. [59–62]. It is not as steep as the one for rock because of the lower muon energy loss in water.

26.4.2. Neutrinos:

Because neutrinos have small interaction cross sections, measurements of atmospheric neutrinos require a deep detector to avoid backgrounds. There are two types of measurements: contained (or semi-contained) events, in which the vertex is determined to originate inside the detector, and neutrino-induced muons. The latter are muons that enter the detector from zenith angles so large (e.g., nearly horizontal or upward) that they cannot be muons produced in the atmosphere. In neither case is the neutrino flux measured directly. What is measured is a convolution of the neutrino flux and cross section with the properties of the detector (which includes the surrounding medium in the case of entering muons).

Contained and semi-contained events reflect neutrinos in the sub-GeV to multi-GeV region where the product of increasing cross section and decreasing flux is maximum. In the GeV region the neutrino flux and its angular distribution depend on the geomagnetic location of the detector and, to a lesser extent, on the phase of the solar cycle. Naively, we expect $\nu_{\mu}/\nu_{e}=2$ from counting neutrinos of the two flavors coming from the chain of pion and muon decay. Contrary to expectation, however, the numbers of the two classes of events are similar rather than different by a factor of two. This is now understood to be a consequence of neutrino flavor oscillations [70]. (See the article on neutrino properties in this Review.)

Two well-understood properties of atmospheric cosmic rays provide a standard for comparison of the measurements of atmospheric neutrinos to expectation. These are the "sec θ effect" and the "eastwest effect" [69]. The former refers originally to the enhancement of the flux of > 10 GeV muons (and neutrinos) at large zenith angles because the parent pions propagate more in the low density

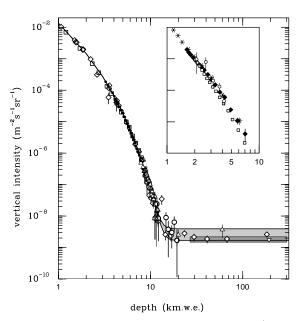

Figure 26.6: Vertical muon intensity vs depth (1 km.w.e. = 10^5 g cm⁻²of standard rock). The experimental data are from: \Diamond : the compilations of Crouch [58], \Box : Baksan [63], \circ : LVD [64], \bullet : MACRO [65], \blacksquare : Frejus [66], and \triangle : SNO [67]. The shaded area at large depths represents neutrino-induced muons of energy above 2 GeV. The upper line is for horizontal neutrino-induced muons, the lower one for vertically upward muons. Darker shading shows the muon flux measured by the SuperKamiokande experiment. The inset shows the vertical intensity curve for water and ice published in Refs. [59–62].

upper atmosphere where decay is enhanced relative to interaction. For neutrinos from muon decay, the enhancement near the horizontal becomes important for $E_{\nu}>1$ GeV and arises mainly from the increased pathlength through the atmosphere for muon decay in flight. Fig. 26.7 from Ref. 68 shows a comparison between measurement and expectation for the zenith angle dependence of multi-GeV electron-like (mostly ν_e) and muon-like (mostly ν_{μ}) events separately. The ν_e show an enhancement near the horizontal and approximate equality for nearly upward ($\cos\theta\approx-1$) and nearly downward ($\cos\theta\approx1$) events. There is, however, a very significant deficit of upward ($\cos\theta<0$) ν_{μ} events, which have long pathlengths comparable to the radius of the Earth. This feature is the principal signature for oscillations [70].

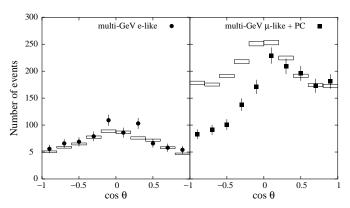

Figure 26.7: Zenith-angle dependence of multi-GeV neutrino interactions from SuperKamiokande [68]. The shaded boxes show the expectation in the absence of any oscillations.

Muons that enter the detector from outside after production in charged-current interactions of neutrinos naturally reflect a higher energy portion of the neutrino spectrum than contained events because

Table 26.3: Measured fluxes $(10^{-9} \text{ m}^{-2} \text{ s}^{-1} \text{ sr}^{-1})$ of neutrino-induced muons as a function of the effective minimum muon energy E_{μ} .

| $E_{\mu} >$ | · 1 GeV | 1 GeV | 1 GeV | 2 GeV | 3 GeV | 3 GeV |
|-------------|-----------------|-----------------|-----------------|-------------------|-------------------|-----------------|
| Ref. | CWI [71] | Baksan [72] | MACRO [73] | IMB [74] | Kam [75] | SuperK [76] |
| F_{μ} | $2.17{\pm}0.21$ | 2.77 ± 0.17 | 2.29 ± 0.15 | $2.26 {\pm} 0.11$ | $1.94 {\pm} 0.12$ | $1.74{\pm}0.07$ |

the muon range increases with energy as well as the cross section. The relevant energy range is $\sim 10 < E_{\nu} < 1000$ GeV, depending somewhat on angle. Neutrinos in this energy range show a $\sec\theta$ effect similar to muons (see Eq. (26.4)). This causes the flux of horizontal neutrino-induced muons to be approximately a factor two higher than the vertically upward flux. The upper and lower edges of the horizontal shaded region in Fig. 26.6 correspond to horizontal and vertical intensities of neutrino-induced muons. Table 26.3 gives the measured fluxes of upward-moving neutrino-induced muons averaged over the lower hemisphere. Generally the definition of minimum muon energy depends on where it passes through the detector. The tabulated effective minimum energy estimates the average over various accepted trajectories.

26.5. Air showers

So far we have discussed inclusive or uncorrelated fluxes of various components of the cosmic radiation. An air shower is caused by a single cosmic ray with energy high enough for its cascade to be detectable at the ground. The shower has a hadronic core, which acts as a collimated source of electromagnetic subshowers, generated mostly from $\pi^0 \to \gamma \gamma$ decays. The resulting electrons and positrons are the most numerous charged particles in the shower. The number of muons, produced by decays of charged mesons, is an order of magnitude lower. Air showers spread over a large area on the ground, and arrays of detectors operated for long times are useful for studying cosmic rays with primary energy $E_0 > 100$ TeV, where the low flux makes measurements with small detectors in balloons and satellites difficult.

Greisen [77] gives the following approximate expressions for the numbers and lateral distributions of particles in showers at ground level. The total number of muons N_{μ} with energies above 1 GeV is

$$N_{\mu}(> 1 \text{ GeV}) \approx 0.95 \times 10^5 \left(N_e/10^6\right)^{3/4} ,$$
 (26.8)

where N_e is the total number of charged particles in the shower (not just e^{\pm}). The number of muons per square meter, ρ_{μ} , as a function of the lateral distance r (in meters) from the center of the shower is

$$\rho_{\mu} = \frac{1.25 \, N_{\mu}}{2\pi \, \Gamma(1.25)} \left(\frac{1}{320}\right)^{1.25} \, r^{-0.75} \, \left(1 + \frac{r}{320}\right)^{-2.5} \, , \tag{26.9}$$

where Γ is the gamma function. The number density of charged particles is

$$\rho_e = C_1(s, d, C_2) x^{(s-2)} (1+x)^{(s-4.5)} (1+C_2 x^d) . \tag{26.10}$$

Here s, d, and C_2 are parameters in terms of which the overall normalization constant $C_1(s,d,C_2)$ is given by

$$C_1(s, d, C_2) = \frac{N_e}{2\pi r_1^2} [B(s, 4.5 - 2s) + C_2 B(s + d, 4.5 - d - 2s)]^{-1},$$
(26.11)

where B(m,n) is the beta function. The values of the parameters depend on shower size (N_e) , depth in the atmosphere, identity of the primary nucleus, etc. For showers with $N_e \approx 10^6$ at sea level, Greisen uses s=1.25, d=1, and $C_2=0.088$. Finally, x is r/r_1 , where r_1 is the Molière radius, which depends on the density of the atmosphere and hence on the altitude at which showers are detected. At sea level $r_1 \approx 78$ m. It increases with altitude as the air density decreases. (See

the section on electromagnetic cascades in the article on the passage of particles through matter in this Review).

The lateral spread of a shower is determined largely by Coulomb scattering of the many low-energy electrons and is characterized by the Molière radius. The lateral spread of the muons (ρ_{μ}) is larger and depends on the transverse momenta of the muons at production as well as multiple scattering.

There are large fluctuations in development from shower to shower, even for showers of the same energy and primary mass—especially for small showers, which are usually well past maximum development when observed at the ground. Thus the shower size N_e and primary energy E_0 are only related in an average sense, and even this relation depends on depth in the atmosphere. One estimate of the relation is [84]

$$E_0 \sim 3.9 \times 10^6 \text{ GeV } (N_e/10^6)^{0.9}$$
 (26.12)

for vertical showers with $10^{14} < E < 10^{17}$ eV at 920 g cm⁻² (965 m above sea level). As E_0 increases the shower maximum (on average) moves down into the atmosphere and the relation between N_e and E_0 changes. Moreover, because of fluctuations, N_e as a function of E_0 is not correctly obtained by inverting Eq. (26.12). At the maximum of shower development, there are approximately 2/3 particles per GeV of primary energy.

There are three common types of air shower detectors: shower arrays that study the shower size N_e and the lateral distribution on the ground, Cherenkov detectors that detect the Cherenkov radiation emitted by the charged particles of the shower, and fluorescence detectors that study the nitrogen fluorescence excited by the charged particles in the shower. The fluorescence light is emitted isotropically so the showers can be observed from the side. Detailed simulations and cross-calibrations between different types of detectors are necessary to establish the primary energy spectrum from air-shower experiments.

Figure 26.8 shows the "all-particle" spectrum. The differential energy spectrum has been multiplied by $E^{2.6}$ in order to display the features of the steep spectrum that are otherwise difficult to discern. The steepening that occurs between 10^{15} and 10^{16} eV is known as the knee of the spectrum. The feature around $10^{18.5}$ eV is called the ankle of the spectrum.

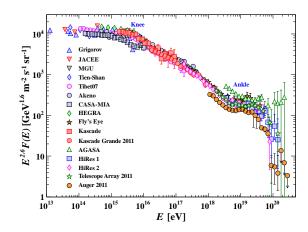

Figure 26.8: The all-particle spectrum as a function of E (energy-per-nucleus) from air shower measurements [79–90,100–104].

Measurements of flux with small air shower experiments in the knee region differ by as much as a factor of two, indicative of systematic uncertainties in interpretation of the data. (For a review see Ref. 78.) In establishing the spectrum shown in Fig. 26.8, efforts have been made to minimize the dependence of the analysis on the primary composition. Ref. 87 uses an unfolding procedure to obtain the spectra of the individual components, giving a result for the all-particle spectrum between 10¹⁵ and 10¹⁷ eV that lies toward the upper range of the data shown in Fig. 26.8. In the energy range above 10¹⁷ eV, the fluorescence technique [89] is particularly useful because it can establish the primary energy in a model-independent way by observing most of the longitudinal development of each shower, from which E_0 is obtained by integrating the energy deposition in the atmosphere. The result, however, depends strongly on the light absorption in the atmosphere and the calculation of the detector's aperture.

Assuming the cosmic ray spectrum below 10^{18} eV is of galactic origin, the *knee* could reflect the fact that most cosmic accelerators in the galaxy have reached their maximum energy. Some types of expanding supernova remnants, for example, are estimated not to be able to accelerate protons above energies in the range of 10^{15} eV. Effects of propagation and confinement in the galaxy [91] also need to be considered. The KASCADE-Grande experiment [90] has reported observation of a second steepening of the spectrum near 8×10^{16} eV, with evidence that this structure is accompanied a transition to heavy primaries.

Concerning the ankle, one possibility is that it is the result of a higher energy population of particles overtaking a lower energy population, for example an extragalactic flux beginning to dominate over the galactic flux (e.g. Ref. 89). Another possibility is that the dip structure in the region of the ankle is due to $\gamma p \rightarrow e^+ + e^-$ energy losses of extragalactic protons on the 2.7 K cosmic microwave radiation (CMB) [93]. This dip structure has been cited as a robust signature of both the protonic and extragalactic nature of the highest energy cosmic rays [92]. If this interpretation is correct, then the galactic cosmic rays do not contribute significantly to the flux above 10^{18} eV, consistent with the maximum expected range of acceleration by supernova remnants.

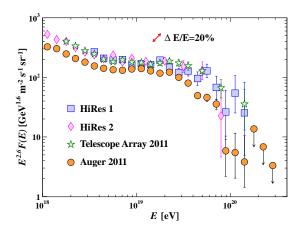

Figure 26.9: Expanded view of the highest energy portion of the cosmic-ray spectrum from data of HiRes 1&2 [101], the Telescope Array [103], and the Auger Observatory [104]. The HiRes stereo spectrum [112] is consistent with the HiRes 1&2 monocular results. The differential cosmic ray flux is multiplied by $E^{2.6}$. The red arrow indicates the change in the plotted data for a systematic shift in the energy scale of 20%.

The energy-dependence of the composition from the knee through the ankle is useful in discriminating between these two viewpoints, since a heavy composition above 10^{18} eV is inconsistent with the formation of the ankle by pair production losses on the CMB.

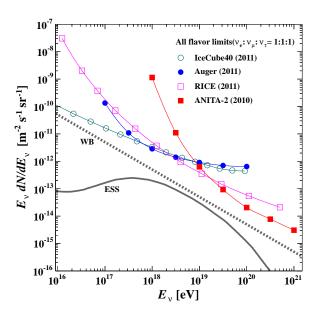

Figure 26.10: Differential limits on the flux of cosmogenic neutrinos set by four neutrino experiments. The curves show the Waxman-Bahcall benchmark flux (WB, [111]) and a representative midrange model for the expected flux of cosmogenic neutrinos (ESS, [110]). The expected flux is uncertain by over an order of magnitude in either direction.

The HiRes and Auger experiments, however, present very different interpretations of data on the depth of shower maximum X_{max} , a quantity that correlates strongly with the interaction cross section of the primary particle. If these results are interpreted using standard extrapolations of measured proton and nuclear cross sections, then the HiRes data [94] is consistent with the ultrahigh-energy cosmic ray (UHECR) composition getting lighter and containing only protons and helium above 10^{19} eV, while Auger [95,96] sees a composition getting lighter up to 2×10^{18} eV and becoming heavier after that, intermediate between protons and iron at 3×10^{19} eV. This may mean that the extragalactic cosmic rays have a mixed composition at acceleration similar to the GeV galactic cosmic rays. It is important to note that the measurements of X_{max} may be interpreted with equal validity in terms of a changing proton-air cross-section and no change in composition.

If the cosmic ray flux at the highest energies is cosmological in origin, there should be a rapid steepening of the spectrum (called the GZK feature) around 5×10^{19} eV, resulting from the onset of inelastic interactions of UHE cosmic rays with the cosmic microwave background [97,98]. Photo-dissociation of heavy nuclei in the mixed composition model [99] would have a similar effect. UHECR experiments have detected events of energy above 10^{20} eV [89,100–102]. The AGASA experiment [100] did not observe the expected GZK feature. The HiRes fluorescence experiment [101,112] has detected evidence of the GZK supression, and the Auger observatory [102–104] has presented spectra showing this supression based on surface detector measurements calibrated against its fluorescence detector using events detected in hybrid mode, i.e. with both the surface and the fluorescence detectors. Recent observations by the Telescope Array [103] also exhibit this supression.

Figure 26.9 gives an expanded view of the high energy end of the spectrum, showing only the more recent data. This figure shows the differential flux multiplied by $E^{2.6}$. The experiments are consistent in normalization if one takes quoted systematic errors in the energy scales into account. The continued power law type of flux beyond the GZK cutoff previously claimed by the AGASA experiment [100] is not supported by the HiRes, Telescope Array, and Auger data.

One half of the energy that UHECR protons lose in photoproduction interactions that cause the GZK effects ends up in neutrinos [105].

Measuring this cosmogenic neutrino flux above 10^{18} eV would help resolve the UHECR uncertainties mentioned above. The magnitude of this flux depends strongly on the cosmic ray spectrum at acceleration, the cosmic ray composition, and the cosmological evolution of the cosmic ray sources. In the case that UHECR have mixed composition only the proton fraction would produce cosmogenic neutrinos. Heavy nuclei propagation produces mostly $\bar{\nu}_e$ at lower energy from neutron decay.

The expected rate of cosmogenic neutrinos is lower than current limits obtained by IceCube [106], the Auger observatory [108], RICE [107], and ANITA-2 [109], which are shown in Figure 26.10 together with a model for cosmogenic neutrino production [110] and the Waxman-Bahcall benchmark flux of neutrinos produced in cosmic ray sources [111]. At production, the dominant component of neutrinos comes from π^{\pm} decays and has flavor content $\nu_e:\nu_{\mu}:\nu_{\tau}=1:2:0$. After oscillations, the arriving cosmogenic neutrinos are expected to be an equal mixture of all three flavors. The sensitivity of each experiment depends on neutrino flavor. IceCube, RICE, and ANITA are sensitive to all three flavors, and the sensitivity to different flavors is energy dependent. The limit of Auger is only for ν_{τ} and $\bar{\nu}_{\tau}$ which should be about 1/3 of the total neutrino flux after oscillations, so this limit is plotted multiplied by a factor of three for comparison with the other limits and with the theoretical estimates.

27. ACCELERATOR PHYSICS OF COLLIDERS

Revised July 2011 by D.A. Edwards (DESY) and M.J. Syphers (MSU).

27.1. Luminosity

This article provides background for the High-Energy Collider Parameter Tables that follow. The number of events, N_{exp} , is the product of the cross section of interest, σ_{exp} , and the time integral over the instantaneous luminosity, \mathcal{L} :

$$N_{exp} = \sigma_{exp} \times \int \mathcal{L}(t)dt.$$
 (27.1)

Today's colliders all employ bunched beams. If two bunches containing n_1 and n_2 particles collide head-on with frequency f, a basic expression for the luminosity is

$$\mathcal{L} = f \frac{n_1 n_2}{4\pi \sigma_x \sigma_y} \tag{27.2}$$

where σ_x and σ_y characterize the rms transverse beam sizes in the horizontal (bend) and vertical directions. In this form it is assumed that the bunches are identical in transverse profile, that the profiles are Gaussian and independent of position along the bunch, and the particle distributions are not altered during bunch crossing.

Whatever the distribution at the source, by the time the beam reaches high energy, the normal form is a useful approximation as suggested by the σ -notation. In the case of an electron storage ring, synchrotron radiation leads to a Gaussian distribution in equilibrium, but even in the absence of radiation the central limit theorem of probability and the diminished importance of space charge effects produces a similar result.

The luminosity may be obtained directly by measurement of the beam properties in Eq. (27.2), but the beam measurements are apt to interfere with data acquisition, so this method though valuable to establish collider performance is not suitable for continuous use. A similar expression to Eq. (27.1) with N_{ref} from a known reference cross section, σ_{ref} , may be used to determine σ_{exp} according to $\sigma_{exp} = (N_{exp}/N_{ref})\sigma_{ref}$.

In the Tables, luminosity is stated in units of $\rm cm^{-2}s^{-1}$. Integrated luminosity, on the other hand is usually quoted as the inverse of the standard measures of cross section such as femtobarns and, recently, attoharns

Subsequent sections in this report enlarge briefly on the dynamics behind collider design, comment on the realization of collider performance in a selection of today's facilities, and end with some remarks on future possibilities.

27.2. Beam Dynamics

The first concern of beam dynamics is stability. While a reference particle proceeds along the design, or reference, trajectory other particles in the bunch are to remain close by. Assume that the reference particle carries a right-handed Cartesian coordinate system, with the z-coordinate pointed in the direction of motion along the reference trajectory. The independent variable is the distance s of the reference particle along this trajectory rather than time, and for simplicity this path is taken to be planar. The transverse coordinates are x and y, where $\{x, z\}$ defines the plane of the reference trajectory.

Several time scales are involved, and the approximations used in writing the equations of motion reflect that circumstance. All of today's high energy colliders are alternating gradient synchrotrons [1,2], and the shortest time scale is that associated with transverse stability, the betatron oscillations, so called because of their analysis for the betatron accelerator species years ago. The linearized equations of motion of a particle displaced from the reference particle are

$$x'' + K_x x = 0, K_x \equiv \frac{e}{p} \frac{\partial B}{\partial x} + \frac{1}{\rho^2}$$

$$y'' + K_y y = 0, K_y \equiv -\frac{e}{p} \frac{\partial B}{\partial x}$$

$$z' = -x/\rho$$
(27.3)

where the magnetic field B(s) is only in the y direction, contains only dipole and quadrupole terms, and is treated as static here. The radius of curvature due to the field on the reference orbit is ρ ; p and e are the particle's momentum and charge respectively. The prime denotes d/ds.

The equations for x and y are those of harmonic oscillators but with restoring force periodic in s, that is, they are instances of Hill's equation. The solution may be written in the form

$$x(s) = A_x \sqrt{\beta_x} \cos \psi_x$$

$$x'(s) = -\frac{A_x}{\sqrt{\beta_x}} \left[\alpha \cos \psi_x + \sin \psi_x \right]$$
(27.4)

where A_x is a constant of integration, $\alpha \equiv -(1/2)d\beta_x(s)/ds$, and the envelope of the motion is modulated by the *amplitude function*, β_x . A solution of the same form describes the motion in y. The subscripts will be suppressed in the following discussion.

The amplitude function satisfies

$$2\beta\beta'' - \beta'^2 + 4\beta^2 K = 4, (27.5)$$

and in a region free of magnetic field it should be noted that the solution of Eq. (27.5) is a parabola. Expressing A in terms of x, x' yields

$$A^{2} = \gamma x^{2} + 2\alpha x x' + \beta x'^{2}$$

$$= \frac{1}{\beta} \left[x^{2} + (\alpha x + \beta x')^{2} \right]$$
(27.6)

with $\gamma \equiv (1+\alpha^2)/\beta$. In a single pass system such as a linac, the Courant-Snyder parameters α , β , γ may be selected to match the $x\,x'$ distribution of the input beam; in a recursive system, the parameters are usually defined by the structure rather than by the beam.

The relationships between the parameters and the structure may be seen by treatment of a simple lattice consisting of equally spaced thin lens quadrupoles equal in magnetic field gradient magnitude but alternating in sign. For this discussion, the weak focusing effects of the bending magnets may be neglected. The propagation of $X \equiv \{x, x'\}$ through a repetition period may be written $X_2 = MX_1$, with the matrix M = FODO composed of the matrices

$$F = \begin{pmatrix} 1 & 0 \\ -1/f & 1 \end{pmatrix}, \ D = \begin{pmatrix} 1 & 0 \\ 1/f & 1 \end{pmatrix}, \ O = \begin{pmatrix} 1 & L \\ 0 & 1 \end{pmatrix},$$

where f is the magnitude of the focal length and L the lens spacing. Then

$$M = \begin{pmatrix} 1 + \frac{L}{f} & 2L + \frac{L^2}{f} \\ -\frac{L}{f^2} & 1 - \frac{L}{f} - \frac{L^2}{f^2} \end{pmatrix}. \tag{27.7}$$

The matrix for y is identical in form differing only by a change in sign of terms linear in f. An eigenvector-eigenvalue analysis of the matrix M shows that the motion is stable provided f > L/2. While that criterion is easily met, in practice instability may be caused by many other factors. including the beam-beam interaction itself.

Standard focus-drift-defocus-drift, or FODO, cells such as characterized in simple form by Eq. (27.7) occupy most of the layout of a large collider ring and may be used to set the scale of the amplitude function and related phase advance. Conversion of Eq. (27.4) to a matrix form equivalent to Eq. (27.7) gives

$$M = \begin{pmatrix} c + \alpha s & \beta s \\ -\gamma s & c - \alpha s \end{pmatrix} \tag{27.8}$$

where $c \equiv \cos \Delta \psi$, $s \equiv \sin \Delta \psi$, and the relation between structure and amplitude function is specified by setting the values of the latter to be the same at both ends of the cell. By comparison of Eq. (27.7) and Eq. (27.8) one finds $c = 1 - L^2/(2f^2)$, so the choice $f = L/\sqrt{2}$ would give a phase advance $\Delta \psi$ of 90 degrees for the standard cell. The amplitude function – a maximum at the focusing quadrupole – would then be 2.7L, illustrating the relationship of alternating gradient focusing amplitudes to relatively local aspects of the design. Other functions such as injection, extraction, and HEP experiments

are included by lattice sections matched to the β , α standard cell parameters at the insertion points.

The phase advances according to $d\psi/ds=1/\beta$; that is, β also plays the role of a local $\lambda/2\pi$, and the tune, ν , is the number of such oscillations per turn about the closed path. In the neighborhood of an interaction point (IP), the beam optics of the ring is configured so as to produce a near focus; the value of the amplitude function at this point is designated β^* .

The motion as it develops with s describes an ellipse in $\{x,x'\equiv dx/ds\}$ phase space the area of which is πA^2 , where A is the constant in Eq. (27.4). If the interior of that ellipse is populated by an ensemble of non-interacting particles, that area, given the name *emittance* and denoted by ε , would change only with energy. For a beam with a Gaussian distribution in x,x', the area containing one standard deviation σ_x is the definition of emittance in the Tables:

$$\varepsilon_x \equiv \pi \frac{\sigma_x^2}{\beta_x},\tag{27.9}$$

with a corresponding expression in the other transverse direction, y. This definition includes 39% of the beam. For most of the entries in the Tables the standard deviation is used as the beam radius.

To complete the coordinates used to describe the motion, we take as the variable conjugate to z the fractional momentum deviation $\delta p/p$ from that of the reference particle. Radiofrequency electric fields in the s direction provide a means for longitudinal oscillations, and the frequency determines the bunch length. The frequency of this system appears in the Tables as does the rms value of $\delta p/p$ characterized as "energy spread" of the beam.

For HEP bunch length is a significant quantity for a variety of reasons, but in the present context if the bunch length becomes larger than β^* the luminosity is adversely affected. This is because β grows parabolically as one proceeds away from the interaction point and so the beam size increases thus lowering the contribution to the luminosity from such locations. This is often called the "hourglass" effect.

The other major external electromagnetic field interaction in the single particle context is the production of synchrotron radiation due to centripetal acceleration, given by the Larmor formula multiplied by a relativistic magnification factor of γ^4 [3]. In the case of electron rings this process determines the equilibrium emittance through a balance between radiation damping and excitation of oscillations, and further serves as the barrier to future higher energy versions in this variety of collider.

27.3. Impediments to High Luminosity

Eq. (27.2) can be recast in terms of emittances and amplitude functions as

$$\mathscr{L} = f \frac{n_1 n_2}{4\sqrt{\epsilon_x \, \beta_x^* \, \epsilon_y \, \beta_y^*}} \ . \tag{27.10}$$

So to achieve high luminosity, all one has to do is make high population bunches of low emittance collide at high frequency at locations where the beam optics provides as low values of the amplitude functions as possible.

Such expressions as Eq. (27.10) of the luminosity are special cases of the more general forms available elsewhere [4]. But while there are no fundamental limits to the process, there are certainly challenges. Here we have space to mention only a few of these. The beam-beam tune shift appears in the Tables. A bunch in beam 1 presents a (nonlinear) lens to a particle in beam 2 resulting in changes to the particle's transverse tune with a range characterized by the parameter [4]

$$\xi_{y,2} = \frac{r_e n_1 \beta_{y,2}^*}{2\pi \gamma_2 \sigma_{y,1} (\sigma_{x,1} + \sigma_{y,1})}$$
(27.11)

where $r_e = e^2/(4\pi\varepsilon_0 mc^2)$ is the classical radius of the electron. The transverse oscillations are susceptible to resonant perturbations from a variety of sources such as imperfections in the magnetic guide field, so certain values of the tune must be avoided. Accordingly, the tune spread arising from ξ is limited, but limited to a value difficult to

predict. But a glance at the Tables shows that electrons are more for giving than protons thanks to the damping effects of synchrotron radiation; the ξ -values for the former are about an order of magnitude larger than those for protons.

A subject of present intense interest is the electron-cloud effect [5,6]; actually a variety of related processes come under this heading. They typically involve a buildup of electron density in the vacuum chamber due to emission from the chamber walls stimulated by electrons or photons originating from the beam itself. For instance, there is a process closely resembling the multipacting effects familiar from radiofrequency system commissioning. Low energy electrons are ejected from the walls by photons from positron or proton beam-produced synchrotron radiation. These electrons are accelerated toward a beam bunch, but by the time they reach the center of the vacuum chamber the bunch has gone and so the now-energetic electrons strike the opposite wall to produce more secondaries. These secondaries are now accelerated by a subsequent bunch, and so on. Among the disturbances that this electron accumulation can produce is enhancement of the tune spread within the bunch; the near-cancellation of bunch-induced electric and magnetic fields is no longer in effect.

The benefits of low emittance are clear in Eq. (27.10). For electron synchrotrons, radiation damping provides an automatic route. For hadrons, particularly antiprotons, two inventions have played a prominent role. Stochastic cooling [7] was employed first in the $S\bar{p}pS$ and subsequently in the Tevatron. Electron cooling [8] was also used in the Tevatron complex to great advantage. Further innovations are underway due to the needs of potential future projects; these are noted in the final section.

27.4. Comments on Present Facilities

Collider accelerator physics of course goes far beyond the elements of the preceding sections. In this section elaboration is made on various issues associated with some of the recently operating colliders, particularly factors which impact integrated luminosity. The various colliders utilizing hadrons have important unique differences and hence are broken out separately. As space is limited, general references are provided where much further information can be obtained.

27.4.1. LHC: [9] The superconducting Large Hadron Collider is the world's highest energy collider. Operation for HEP is currently conducted with 3.5 TeV protons in each beam. Progress is rapid and current status is best checked at the Web site referenced in the heading of this subsection. To meet its luminosity goals the LHC will have to contend with a high beam current of 0.5 A, leading to stored energies of several hundred MJ per beam. Component protection, beam collimation, and controlled energy deposition will be given very high priorities. Additionally, at energies of 5-7 TeV per particle, synchrotron radiation will move from being a curiosity to a challenge in a hadron accelerator for the first time. At design beam current the system must remove roughly 7 kW at 1.8 K due to synchrotron radiation. As the photons are emitted their interactions with the vacuum chamber wall can generate free electrons, with consequent "electron cloud" development. Much care was taken to design a special liner for the chamber to mitigate this issue.

The two proton beams are contained in separate pipes throughout most of the circumference, but naturally must be brought together into a single pipe at the interaction points. The large number of bunches, and subsequent short bunch spacing, would lead to approximately 30 head-on collisions through 120 m of common beam pipe at each IP. Thus, a small crossing angle is employed, which reduces the luminosity by about 15%. Still, the bunches moving in one direction will have long-range encounters with the counter-rotating bunches and the resulting perturbations of the particle motion constitute a continued course of study. Initial luminosity measurements were made by the "van der Meer scan" as was done long ago on the ISR [10]. The detectors will have measurements based on a reference cross section; for an example see the discussion in the ATLAS design report [11]. The Tables also show the performance anticipated for Pb-Pb collisions. The ALICE [12] experiment is designed to concentrate on these high energy-density phenomena.

In the coming years, an ambitious upgrade program, Super LHC [13], has as its target an order-of-magnitude increase in luminosity.

27.4.2. *Tevatron*: [14] The first superconducting synchrotron in history, the Tevatron was the highest energy collider for 25 years. Operation was terminated in September 2011. The route to high integrated luminosity in the Tevatron was governed by the antiproton production rate, the turn-around time to produce another store, and the resulting optimization of store time. The overall reliability of the accelerator complex plays a crucial role, as it can take many hours to produce an adequate number of antiprotons for collisions.

Unlike the LHC, the beams in the Tevatron circulated in a single vacuum pipe and thus were placed on separated orbits which wrap around each other in a helical pattern outside of the interaction regions. Hence, long-range encounters played an important role here as well, though the effects could be different from the LHC where the encounters are more or less "in phase" with each other through a single interaction region. In the Tevatron, the 70 long-range encounters were distributed about the synchrotron and their mitigation was limited by the available aperture.

In recent years the antiproton bunch intensities approached those of the proton bunches, and their emittances were greatly reduced using improved beam cooling, so much so that detrimental effects on the proton beam became apparent. The antiproton beam emittance was adjusted prior to collision conditions to optimize the proton bunch lifetime during the store [15]. The Tevatron ultimately achieved luminosities a factor of 400 over the original design specification.

27.4.3. e^+e^- Rings: As should be expected, synchrotron radiation plays a major role in the design and optimization of e^+e^- colliders. While vacuum stability and electron clouds can be of concern in the positron rings, synchrotron radiation along with the restoration of longitudinal momentum by the RF system have the positive effect of generating very small transverse beam sizes and small momentum spread. Further reduction of beam size at the interaction points using standard beam optics techniques and successfully contending with high beam currents has led to record luminosities in these rings, far exceeding those of hadron colliders. To maximize integrated luminosity the beam can be "topped off" by injecting new particles without removing existing ones — a feature difficult to imitate in hadron colliders.

Asymmetric energies of the two beams have allowed for the enhancement of B-physics research and for interesting interaction region designs. As the bunch spacing can be quite short, the lepton beams sometimes pass through each other at an angle and hence have reduced luminosity. Recently, however, the invention of high frequency "crab crossing" schemes have produced full restoration of the luminous region. KEK-B has attained over 1 fb⁻¹ of integrated luminosity in a single day, and its upgrade plans are aiming for initial luminosities of $8 \times 10^{35} \, \mathrm{cm}^{-2} \mathrm{s}^{-1}$ [16].

27.4.4. HERA: [17] Now decommissioned, HERA was the first facility to employ both applications of superconductivity: magnets and accelerating structures. Its next-generation cold-iron superconducting magnets for the proton beam were the culmination of lessons learned from the Tevatron experience and extensive development of the technology since then. The HERA team felt comfortable with a larger dynamic range of the magnet system, enabling the use of the existing DESY complex for injection. Though the HERA magnets could reach fields consistent with energies above 1 TeV, other accelerator systems precluded operation above 920 GeV.

The lepton beams (positrons or electrons) were provided by the existing complex, and were accelerated to 27.5 GeV using conventional magnets. The interaction region where the beams had common vacuum chambers had the interesting feature that the lepton beam could be manipulated without detrimental effects on the proton beam due to the large difference in magnetic rigidity. A 4-times higher frequency RF system was used at collision to generate shorter bunches, thus helping alleviate the hour glass effect at the collision points. As in any high energy lepton storage ring, the lepton beam naturally would become transversely polarized (within about 40 minutes, for

HERA). "Spin rotators" were implemented on either side of an IP to produce longitudinal polarization at the experiment.

27.4.5. *RHIC*: [18] The Relativistic Heavy Ion Collider employs superconducting magnets, and collides combinations of fully-stripped ions such as H-H (p-p), Au-Au, Cu-Cu, and d-Au.

The high charge per particle (+79 for gold, for instance) makes intra-beam scattering of particles within the bunch of special concern, even for seemingly modest bunch intensities. Another special feature of accelerating heavy ions in RHIC is that the beams experience a "transition energy" during acceleration – a point where the derivative with respect to momentum of the revolution period is zero. This is more typical of low-energy accelerators, where the necessary phase jump required of the RF system is implemented rapidly and little time is spent near this condition. In the case of RHIC with heavy ions, the superconducting magnets do not ramp very quickly and the period of time spent crossing transition is long and must be dealt with carefully. For p-p operation the beams are always above their transition energy and so this condition is completely avoided.

RHIC is also distinctive in its ability to accelerate and collide polarized proton beams. As proton beam polarization must be maintained from its low-energy source, successful acceleration through the myriad of depolarizing resonance conditions in high energy circular accelerators has taken years to accomplish. An energy of 250 GeV per proton with $\sim 48\%$ final polarization per beam has been realized.

27.5. Future Prospects

Present design activity emphasizes a lepton collider as the next major HEP project contingent upon the initial results from the LHC. Synchrotron radiation precludes a higher energy successor to LEP. Four alternatives are noted in this section: two approaches to an electron-positron linear collider, a muon ring collider, and potential use of plasma acceleration.

27.5.1. Electron-Positron Linear Colliders: A major problem confronting a high energy, high luminosity single pass collider design is the power requirement, so measures must be taken to keep the demand within bounds as illustrated in a transformed Eq. (27.2) as developed in the TESLA Design Report [19]:

$$\mathcal{L} = \frac{1}{4\pi r_e^{3/2}} \frac{P_b}{E_{cm}} \left(\frac{\pi \delta_E}{\gamma \varepsilon_y}\right)^{1/2} H_D. \tag{27.12}$$

Here, P_b is the total power of both beams and E_{cm} their cms energy. Management of P_b leads to an upward push on the product of collision frequency and bunch population with an attendant rise in the energy radiated due to the electromagnetic field of one bunch acting on the particles of the other. The fractional spread in the collision energy that results from this radiation is represented by δ_E and keeping a significant fraction of the luminosity within a percent or so of the nominal energy represents a design goal. A consequence is the use of flat beams, where δ_E is managed by the beam width, and luminosity adjusted by the beam height, thus the explicit appearance of the vertical emittance ε_y . The final factor in Eq. (27.12), H_D , represents the enhancement of luminosity due to the pinch effect during bunch crossing.

The approach designated by the International Linear Collider (ILC) is presented in the Tables, and the contrast with the collision-point parameters of the circular colliders is striking, though reminiscent in direction of those of the SLAC Linear Collider that are no longer shown. The ILC Reference Design Report [20] has a baseline cms energy of 500 GeV with upgrade provision for 1 TeV, and luminosity comparable to the LHC. The ILC is based on superconducting accelerating structures of the 1.3 GHz TESLA variety.

At CERN, a design effort is underway on the Compact Linear Collider (CLIC), each linac of which is itself a two-beam accelerator, in that a high energy, low current beam is fed by a low energy, high current driver [21]. The CLIC design employs normal conducting 12 GHz accelerating structures at a gradient of 100 MeV/m, some three times the current capability of the superconducting ILC cavities. The design cms energy is 3 TeV.

27.5.2. Muon Collider: The muon to electron mass ratio of 210 implies less concern about synchrotron radiation by a factor of about 2×10^9 and its 1.6 μ s lifetime means that it will last for some 150B turns in a ring about half of which is occupied by bend magnets with average field B (tesla). Design effort became serious in the mid 1990s and a collider outline emerged quickly [22].

Removal of the synchrotron radiation barrier reduces collider facility scale to a level compatible with on-site placement at some locations. If a Higgs particle is detected the $(m_{\mu}/m_e)^2$ cross section advantage in s-channel production would be valuable. And a neutrino factory could potentially be realized in the course of construction [23].

The challenges to luminosity achievement were clear and very attractive for R&D: targetting, collection, and emittance reduction are three that come immediately to mind. The proton source needs to deliver a beam power of several MW, collection would be aided by magnetic fields common on neutron stars (though scaled back for application on earth), and the emittance requirements have inspired fascinating investigations into phase space manipulation that are finding application in other facilities. A summary of the status may be found in a presentation to the HEPAP P5 Panel [24].

27.5.3. Plasma Acceleration: At the 1956 CERN Symposium, a paper by Veksler in which he suggested acceleration of protons to the TeV scale using a bunch of electrons anticipated current interest in plasma acceleration [25]. A half-century later this is more than a suggestion, with the demonstration, as a striking example, of energy enhancement of 28.5 GeV at SLAC [26].

How plasma acceleration will find application in an HEP facility is not yet clear, given the necessity of coordinating multiple plasma chambers. Active R&D is underway; for recent discussion of parameters for a laser-plasma based electron positron collider, see, for example, relevant papers in an Advanced Accelerator Concepts Workshop [27].

HIGH-ENERGY COLLIDER PARAMETERS: e^+e^- Colliders (I)

Updated in early 2012 with numbers received from representatives of the colliders (contact J. Beringer, LBNL). The table shows parameter values as achieved by January 1, 2012. Quantities are, where appropriate, r.m.s.; unless noted otherwise, energies refer to beam energy; H and V indicate horizontal and vertical directions; s.c. stands for superconducting. Parameters for the defunct SPEAR, DORIS, PETRA, PEP, SLC, TRISTAN, and VEPP-2M colliders may be found in our 1996 edition (Phys. Rev. **D54**, 1 July 1996, Part I).

 $^{{}^{*}}$ With dynamic beam-beam effect.

HIGH-ENERGY COLLIDER PARAMETERS: $ep, \overline{p}p, pp$ Colliders

Updated in early 2012 with numbers received from representatives of the colliders (contact J. Beringer, LBNL). The table shows parameter values as achieved by January 1, 2012. For LHC, the parameters expected for running in 2012 and nominal values are also given. Quantities are, where appropriate, r.m.s.; unless noted otherwise, energies refer to beam energy; H and V indicate horizontal and vertical directions; s.c. stands for superconducting; pk and avg denote peak and average values.

29. NEUTRINO BEAM LINES AT HIGH-ENERGY PROTON SYNCHROTRONS

Created in May 2012 with numbers verified by representatives of the synchrotrons (contact C.-J. Lin, LBNL). For existing (future) neutrino beam lines the latest achieved (design) values are given.

The main source of neutrinos at proton synchrotrons is from the decay of pions and kaons produced by protons striking a nuclear target. There are different schemes to focus the secondary particles to enhance neutrino flux and/or tune the neutrino energy profile. In wide-band beams (WBB), the neutrino parent mesons are focused over a wide momentum range to obtain maximum neutrino intensity. In narrow-band beams (NBB), the secondary particles are first momentum-selected to produce a monochromatic parent beam. Another approach to generate a narrow-band neutrino spectrum is to select neutrinos that decay off-axis relative to the momentum of the parent mesons. For a comprehensive review of the topic, including other historical neutrino beam lines, see the article by S. E. Kopp, "Accelerator-based neutrino beams," Phys. Rept. 439, 101 (2007).

30.1. Notation

Table 30.1: Summary of variables used in this section. The kinematic variables β and γ have their usual meanings.

| Symbol | Definition | Units or Value |
|---------------------|---------------------------------------------|------------------------------------------------------------------|
| α | Fine structure constant | 1/137.035 999 11(46) |
| | $(e^2/4\pi\epsilon_0\hbar c)$ | |
| M | Incident particle mass | MeV/c^2 |
| E | Incident part. energy γMc^2 | MeV |
| T | Kinetic energy | MeV |
| $m_e c^2$ | Electron mass $\times c^2$ | $0.510998918(44)\mathrm{MeV}$ |
| r_e | Classical electron radius | 2.817940325(28) fm |
| | $e^2/4\pi\epsilon_0 m_e c^2$ | |
| N_A | Avogadro's number | $6.0221415(10) \times 10^{23} \text{ mol}^{-1}$ |
| ze | Charge of incident particle | |
| Z | Atomic number of absorber | |
| A | Atomic mass of absorber | $g \text{ mol}^{-1}$ |
| K/A | $4\pi N_A r_e^2 m_e c^2/A$ | $0.307075 \text{ MeV g}^{-1} \text{ cm}^2$ |
| | | for $A = 1 \text{ g mol}^{-1}$ |
| I | Mean excitation energy | eV (Nota bene!) |
| $\delta(eta\gamma)$ | Density effect correction to ic | |
| $\hbar\omega_p$ | Plasma energy | $\sqrt{\rho \langle Z/A \rangle} \times 28.816 \text{ eV}$ |
| | $(\sqrt{4\pi N_e r_e^3} \ m_e c^2/\alpha)$ | $(\rho \text{ in g cm}^{-3})$ |
| N_e | Electron density | (units of r_e) ⁻³ |
| w_{j} | Weight fraction of the j th ele | ement in a compound or mixture |
| n_{j} | | ns in a compound or mixture |
| | $4\alpha r_e^2 N_A / A \qquad (716.408)$ | $(g \text{ cm}^{-2})^{-1} \text{ for } A = 1 \text{ g mol}^{-1}$ |
| X_0 | Radiation length | $\mathrm{g~cm^{-2}}$ |
| E_c | Critical energy for electrons | MeV |
| $E_{\mu c}$ | Critical energy for muons | GeV |
| $\dot{E_s}$ | Scale energy $\sqrt{4\pi/\alpha} \ m_e c^2$ | $21.2052~\mathrm{MeV}$ |
| R_M | Molière radius | $\mathrm{g}\;\mathrm{cm}^{-2}$ |

30.2. Electronic energy loss by heavy particles [1–34]

30.2.1. Moments and cross sections:

The electronic interactions of fast charged particles with speed $v=\beta c$ occur in single collisions with energy losses E [1], leading to ionization, atomic, or collective excitation. Most frequently the energy losses are small (for 90% of all collisions the energy losses are less than 100 eV). In thin absorbers few collisions will take place and the total energy loss will show a large variance [1]; also see Sec. 30.2.7 below. For particles with charge ze more massive than electrons ("heavy" particles), scattering from free electrons is adequately described by the Rutherford differential cross section [2], * †

$$\frac{d\sigma_R(E;\beta)}{dE} = \frac{2\pi r_e^2 m_e c^2 z^2}{\beta^2} \frac{(1-\beta^2 E/T_{\rm max})}{E^2} , \qquad (30.1)$$

where $T_{\rm max}$ is the maximum energy transfer possible in a single collision. But in matter electrons are not free. E must be finite and depends on atomic and bulk structure. For electrons bound

^{*} For spin 0 particles. The β dependence in the parentheses is different for spin 1/2 and spin 1 particles, but it is not important except at energies far above atomic binding energies.

 $^{^{\}dagger}$ In high-energy physics E normally means total energy, $T+mc^2$. In stopping power discussions, E means kinetic energy, and we follow that convention (with some inconsistency).

in atoms Bethe [3] used "Born Theorie" to obtain the differential cross section

$$\frac{d\sigma_B(E;\beta)}{dE} = \frac{d\sigma_R(E,\beta)}{dE}B(E) \ . \tag{30.2}$$

Examples of B(E) and $d\sigma_B/dE$ can be seen in Figs. 5 and 6 of Ref. 1.

of a few %. With the symbol definitions and values given in Table 30.1, the units are MeV $g^{-1}cm^2$. At the lower limit the projectile velocity becomes comparable to atomic electron "velocities" (Sec. 30.2.3), and at the upper limit radiative effects begin to be important (Sec. 30.6). Both limits are Z dependent.

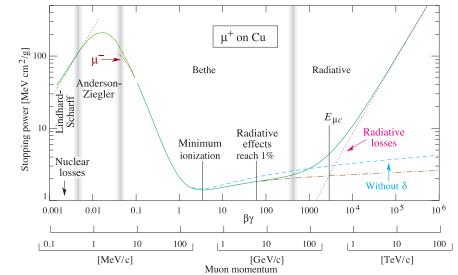

Fig. 30.1: Stopping power (= $\langle -dE/dx \rangle$) for positive muons in copper as a function of $\beta \gamma = p/Mc$ over nine orders of magnitude in momentum (12 orders of magnitude in kinetic energy). Solid curves indicate the total stopping power. Data below the break at $\beta \gamma \approx 0.1$ are taken from ICRU 49 [4], and data at higher energies are from Ref. 5. Vertical bands indicate boundaries between different approximations discussed in the text. The short dotted lines labeled " μ " illustrate the "Barkas effect," the dependence of stopping power on projectile charge at very low energies [6].

Bethe's theory extends only to some energy above which atomic effects were not important. The free-electron cross section (Eq. (30.1)) can be used to extend the cross section to $T_{\rm max}$. At high energies σ_B is further modified by polarization of the medium, and this "density effect," discussed in Sec. 30.2.4, must also be included. Less important corrections are discussed below

The mean number of collisions with energy loss between E and E+dE occurring in a distance δx is $N_e \delta x \, (d\sigma/dE) dE$, where $d\sigma(E;\beta)/dE$ contains all contributions. It is convenient to define the moments

$$M_j(\beta) = N_e \, \delta x \int E^j \frac{d\sigma(E;\beta)}{dE} dE , \qquad (30.3)$$

so that M_0 is the mean number of collisions in δx , M_1 is the mean energy loss in δx , $M_2-M_1^2$ is the variance, etc. The number of collisions is Poisson-distributed with mean M_0 . N_e is either measured in electrons/g ($N_e=N_AZ/A$) or electrons/cm³ ($N_e=N_A\,\rho Z/A$). The former is used throughout this chapter, since quantities of interest (dE/dx, X_0 , etc.) vary smoothly with composition when there is no density dependence.

30.2.2. Stopping power at intermediate energies:

The mean rate of energy loss by moderately relativistic charged heavy particles, $M_1/\delta x$, is well-described by the "Bethe" equation,

$$-\left\langle \frac{dE}{dx}\right\rangle = Kz^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\frac{1}{2} \ln \frac{2m_e c^2 \beta^2 \gamma^2 T_{\text{max}}}{I^2} - \beta^2 - \frac{\delta(\beta \gamma)}{2} \right]. \tag{30.4}$$

It describes the mean rate of energy loss in the region $0.1\lesssim \beta\gamma\lesssim 1000$ for intermediate-Z materials with an accuracy

Here $T_{\rm max}$ is the maximum kinetic energy which can be imparted to a free electron in a single collision, and the other variables are defined in Table 30.1. A minor dependence on M at the highest energies is introduced through $T_{\rm max}$, but for all practical purposes $\langle dE/dx \rangle$ in a given material is a function of β alone.

For heavy projectiles, like ions, additional terms are required to account for higher-order photon coupling to the target, and to account for the finite size of the target radius. These can change dE/dx by a factor of two or more for the heaviest nuclei in certain kinematic regimes [7].

Few concepts in high-energy physics are as misused as $\langle dE/dx \rangle$. The main problem is that the mean is weighted by very rare events with large single-collision energy deposits. Even with samples of hundreds of events a dependable value for the mean energy loss cannot be obtained. Far better and more easily measured is the most probable energy loss, discussed in Sec. 30.2.7. The most probable energy loss in a detector is considerably below the mean given by the Bethe equation.

In a TPC (Sec. 31.6.5), the mean of 50%–70% of the samples with the smallest signals is often used as an estimator.

Although it must be used with cautions and caveats, $\langle dE/dx \rangle$ as described in Eq. (30.4) still forms the basis of much of our understanding of energy loss by charged particles. Extensive tables are available[5,4, pdg.lbl.gov/AtomicNuclearProperties/].

The function as computed for muons on copper is shown as the "Bethe" region of Fig. 30.1. Mean energy loss behavior below this region is discussed in Sec. 30.2.3, and the radiative effects at high energy are discussed in Sec. 30.6. Only in the Bethe region is it a function of β alone; the mass dependence

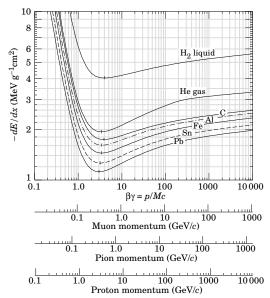

Figure 30.2: Mean energy loss rate in liquid (bubble chamber) hydrogen, gaseous helium, carbon, aluminum, iron, tin, and lead. Radiative effects, relevant for muons and pions, are not included. These become significant for muons in iron for $\beta\gamma\gtrsim 1000$, and at lower momenta for muons in higher-Z absorbers. See Fig. 30.23.

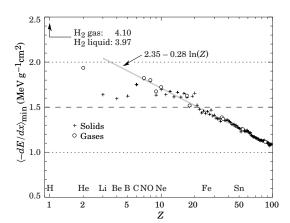

Figure 30.3: Stopping power at minimum ionization for the chemical elements. The straight line is fitted for Z > 6. A simple functional dependence on Z is not to be expected, since $\langle -dE/dx \rangle$ also depends on other variables.

is more complicated elsewhere. The stopping power in several other materials is shown in Fig. 30.2. Except in hydrogen, particles with the same velocity have similar rates of energy loss in different materials, although there is a slow decrease in the rate of energy loss with increasing Z. The qualitative behavior difference at high energies between a gas (He in the figure) and the other materials shown in the figure is due to the density-effect correction, $\delta(\beta\gamma)$, discussed in Sec. 30.2.4. The stopping power functions are characterized by broad minima whose position drops from $\beta\gamma=3.5$ to 3.0 as Z goes from 7 to 100. The values of minimum ionization as a function of atomic number are shown in Fig. 30.3.

In practical cases, most relativistic particles (e.g., cosmic-ray muons) have mean energy loss rates close to the minimum; they are "minimum-ionizing particles," or mip's.

Eq. (30.4) may be integrated to find the total (or partial) "continuous slowing-down approximation" (CSDA) range R for

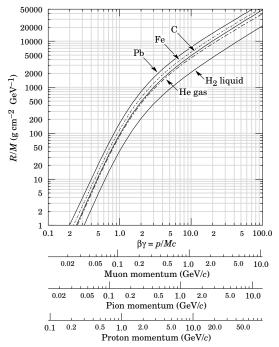

Figure 30.4: Range of heavy charged particles in liquid (bubble chamber) hydrogen, helium gas, carbon, iron, and lead. For example: For a K^+ whose momentum is 700 MeV/c, $\beta\gamma = 1.42$. For lead we read $R/M \approx 396$, and so the range is 195 g cm⁻².

a particle which loses energy only through ionization and atomic excitation. Since dE/dx depends only on β , R/M is a function of E/M or pc/M. In practice, range is a useful concept only for low-energy hadrons ($R \lesssim \lambda_I$, where λ_I is the nuclear interaction length), and for muons below a few hundred GeV (above which radiative effects dominate). R/M as a function of $\beta\gamma = p/Mc$ is shown for a variety of materials in Fig. 30.4.

The mass scaling of dE/dx and range is valid for the electronic losses described by the Bethe equation, but not for radiative losses, relevant only for muons and pions.

For a particle with mass M and momentum $M\beta\gamma c$, $T_{\rm max}$ is given by

$$T_{\text{max}} = \frac{2m_e c^2 \,\beta^2 \gamma^2}{1 + 2\gamma m_e / M + (m_e / M)^2} \,. \tag{30.5}$$

In older references [2,8] the "low-energy" approximation $T_{\rm max}=2m_ec^2\,\beta^2\gamma^2$, valid for $2\gamma m_e/M\ll 1$, is often implicit. For a pion in copper, the error thus introduced into dE/dx is greater than 6% at 100 GeV.

At energies of order 100 GeV, the maximum 4-momentum transfer to the electron can exceed 1 GeV/c, where hadronic structure effects significantly modify the cross sections. This problem has been investigated by J.D. Jackson [9], who concluded that for hadrons (but not for large nuclei) corrections to dE/dx are negligible below energies where radiative effects dominate. While the cross section for rare hard collisions is modified, the average stopping power, dominated by many softer collisions, is almost unchanged.

"The determination of the mean excitation energy is the principal non-trivial task in the evaluation of the Bethe stopping-power formula" [10]. Recommended values have varied substantially with time. Estimates based on experimental stopping-power measurements for protons, deuterons, and alpha particles and on oscillator-strength distributions and dielectric-response functions were given in ICRU 49 [4]. See also ICRU

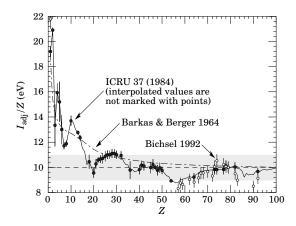

Figure 30.5: Mean excitation energies (divided by Z) as adopted by the ICRU [11]. Those based on experimental measurements are shown by symbols with error flags; the interpolated values are simply joined. The grey point is for liquid H_2 ; the black point at 19.2 eV is for H_2 gas. The open circles show more recent determinations by Bichsel [13]. The dotted curve is from the approximate formula of Barkas [14] used in early editions of this *Review*.

37 [11]. These values, shown in Fig. 30.5, have since been widely used. Machine-readable versions can also be found [12]. These values are widely used.

30.2.3. Energy loss at low energies: Shell corrections C/Z must be included in the square brackets of of Eq. (30.4) [4,11,13,14] to correct for atomic binding having been neglected in calculating some of the contributions to Eq. (30.4). The Barkas form [14] was used in generating Fig. 30.1. For copper it contributes about 1% at $\beta\gamma=0.3$ (kinetic energy 6 MeV for a pion), and the correction decreases very rapidly with increasing energy.

Equation 30.2, and therefore Eq. (30.4), are based on a first-order Born approximation. Higher-order corrections, again important only at lower energies, are normally included by adding the "Bloch correction" $z^2L_2(\beta)$ inside the square brackets (Eq.(2.5) in [4]).

An additional "Barkas correction" $zL_1(\beta)$ reduces the stopping power for a negative particle below that for a positive particle with the same mass and velocity. In a 1956 paper, Barkas *et al.* noted that negative pions had a longer range than positive pions [6]. The effect has been measured for a number of negative/positive particle pairs, including a detailed study with antiprotons [15].

A detailed discussion of low-energy corrections to the Bethe formula is given in ICRU Report 49 [4]. When the corrections are properly included, the Bethe treatment is accurate to about 1% down to $\beta \approx 0.05$, or about 1 MeV for protons.

For $0.01 < \beta < 0.05$, there is no satisfactory theory. For protons, one usually relies on the phenomenological fitting formulae developed by Andersen and Ziegler [4,16]. As shown in ICRU 49 [4] (using data taken from Ref. 16), the nuclear plus electronic proton stopping power in copper is 113 MeV cm² g⁻¹ at T=10 keV, rises to a maximum of 210 MeV cm² g⁻¹ at 100–150 keV, then falls to 120 MeV cm² g⁻¹ at 1 MeV.

For particles moving more slowly than $\approx 0.01c$ (more or less the velocity of the outer atomic electrons), Lindhard has been quite successful in describing electronic stopping power, which is proportional to β [17]. Finally, we note that at even lower energies, e.g., for protons of less than several hundred eV, non-ionizing nuclear recoil energy loss dominates the total energy loss [4,17,18].

30.2.4. Density effect: As the particle energy increases, its electric field flattens and extends, so that the distant-collision contribution to Eq. (30.4) increases as $\ln \beta \gamma$. However, real media become polarized, limiting the field extension and effectively truncating this part of the logarithmic rise [2–8,19–21]. At very high energies,

$$\delta/2 \to \ln(\hbar\omega_p/I) + \ln\beta\gamma - 1/2$$
, (30.6)

where $\delta(\beta\gamma)/2$ is the density effect correction introduced in Eq. (30.4) and $\hbar\omega_p$ is the plasma energy defined in Table 30.1. A comparison with Eq. (30.4) shows that |dE/dx| then grows as $\ln\beta\gamma$ rather than $\ln\beta^2\gamma^2$, and that the mean excitation energy I is replaced by the plasma energy $\hbar\omega_p$. The ionization stopping power as calculated with and without the density effect correction is shown in Fig. 30.1. Since the plasma frequency scales as the square root of the electron density, the correction is much larger for a liquid or solid than for a gas, as is illustrated by the examples in Fig. 30.2.

The density effect correction is usually computed using Sternheimer's parameterization [19]:

$$\delta(\beta\gamma) = \begin{cases} 2(\ln 10)x - \overline{C} & \text{if } x \ge x_1; \\ 2(\ln 10)x - \overline{C} + a(x_1 - x)^k & \text{if } x_0 \le x < x_1; \\ 0 & \text{if } x < x_0 \text{ (nonconductors)}; \\ \delta_0 10^{2(x - x_0)} & \text{if } x < x_0 \text{ (conductors)} \end{cases}$$
(30.7)

Here $x = \log_{10} \eta = \log_{10}(p/Mc)$. \overline{C} (the negative of the C used in Ref. 19) is obtained by equating the high-energy case of Eq. (30.7) with the limit given in Eq. (30.6). The other parameters are adjusted to give a best fit to the results of detailed calculations for momenta below $Mc\exp(x_1)$. Parameters for elements and nearly 200 compounds and mixtures of interest are published in a variety of places, notably in Ref. 21. A recipe for finding the coefficients for nontabulated materials is given by Sternheimer and Peierls [22], and is summarized in Ref. 5.

The remaining relativistic rise comes from the $\beta^2 \gamma^2$ growth of $T_{\rm max}$, which in turn is due to (rare) large energy transfers to a few electrons. When these events are excluded, the energy deposit in an absorbing layer approaches a constant value, the Fermi plateau (see Sec. 30.2.6 below). At extreme energies (e.g., > 332 GeV for muons in iron, and at a considerably higher energy for protons in iron), radiative effects are more important than ionization losses. These are especially relevant for high-energy muons, as discussed in Sec. 30.6.

30.2.5. Energetic knock-on electrons (δ rays): The distribution of secondary electrons with kinetic energies $T \gg I$ is [2]

$$\frac{d^2N}{dTdx} = \frac{1}{2} K z^2 \frac{Z}{A} \frac{1}{\beta^2} \frac{F(T)}{T^2}$$
 (30.8)

for $I \ll T \leq T_{\rm max}$, where $T_{\rm max}$ is given by Eq. (30.5). Here β is the velocity of the primary particle. The factor F is spin-dependent, but is about unity for $T \ll T_{\rm max}$. For spin-0 particles $F(T) = (1-\beta^2 T/T_{\rm max})$; forms for spins 1/2 and 1 are also given by Rossi [2](Sec. 2.3, Eqns. 7 and 8). For incident electrons, the indistinguishability of projectile and target means that the range of T extends only to half the kinetic energy of the incident particle. Additional formulae are given in Ref. 23. Equation (30.8) is inaccurate for T close to I [24].

 δ rays of even modest energy are rare. For a $\beta \approx 1$ particle, for example, on average only one collision with $T_e > 10$ keV will occur along a path length of 90 cm of Ar gas [1].

A δ ray with kinetic energy T_e and corresponding momentum p_e is produced at an angle θ given by

$$\cos \theta = (T_e/p_e)(p_{\text{max}}/T_{\text{max}}) , \qquad (30.9)$$

where p_{max} is the momentum of an electron with the maximum possible energy transfer T_{max} .

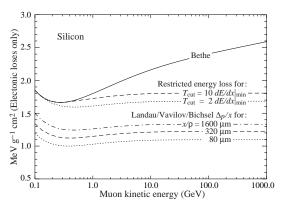

Figure 30.6: Bethe dE/dx, two examples of restricted energy loss, and the Landau most probable energy per unit thickness in silicon. The change of Δ_p/x with thickness x illustrates its $a \ln x + b$ dependence. Minimum ionization $(dE/dx|_{\min})$ is 1.664 MeV g⁻¹ cm². Radiative losses are excluded. The incident particles are muons.

30.2.6. Restricted energy loss rates for relativistic ionizing particles: Further insight can be obtained by examining the mean energy deposit by an ionizing particle when energy transfers are restricted to $T \leq T_{\rm cut} \leq T_{\rm max}$. The restricted energy loss rate is

$$-\frac{dE}{dx}\bigg|_{T < T_{\text{cut}}} = Kz^2 \frac{Z}{A} \frac{1}{\beta^2} \left[\frac{1}{2} \ln \frac{2m_e c^2 \beta^2 \gamma^2 T_{\text{cut}}}{I^2} - \frac{\beta^2}{2} \left(1 + \frac{T_{\text{cut}}}{T_{\text{max}}} \right) - \frac{\delta}{2} \right].$$
(30.10)

This form approaches the normal Bethe function (Eq. (30.4)) as $T_{\rm cut} \to T_{\rm max}$. It can be verified that the difference between Eq. (30.4) and Eq. (30.10) is equal to $\int_{T_{\rm cut}}^{T_{\rm max}} T(d^2N/dTdx)dT$, where $d^2N/dTdx$ is given by Eq. (30.8).

Since $T_{\rm cut}$ replaces $T_{\rm max}$ in the argument of the logarithmic term of Eq. (30.4), the $\beta\gamma$ term producing the relativistic rise in the close-collision part of dE/dx is replaced by a constant, and $|dE/dx|_{T< T_{\rm cut}}$ approaches the constant "Fermi plateau." (The density effect correction δ eliminates the explicit $\beta\gamma$ dependence produced by the distant-collision contribution.) This behavior is illustrated in Fig. 30.6, where restricted loss rates for two examples of $T_{\rm cut}$ are shown in comparison with the full Bethe dE/dx and the Landau-Vavilov most probable energy loss (to be discussed in Sec. 30.2.7 below).

30.2.7. Fluctuations in energy loss: For detectors of moderate thickness x (e.g. scintillators or LAr cells),* the energy loss probability distribution $f(\Delta; \beta \gamma, x)$ is adequately described by the highly-skewed Landau (or Landau-Vavilov) distribution [25,26]. The most probable energy loss is [27]

$$\Delta_p = \xi \left[\ln \frac{2mc^2 \beta^2 \gamma^2}{I} + \ln \frac{\xi}{I} + j - \beta^2 - \delta(\beta \gamma) \right] , \quad (30.11)$$

where $\xi = (K/2) \langle Z/A \rangle (x/\beta^2)$ MeV for a detector with a thickness x in g cm⁻², and j = 0.200 [27]. † While dE/dx is independent of thickness, Δ_p/x scales as $a \ln x + b$. The density correction $\delta(\beta\gamma)$ was not included in Landau's or Vavilov's work, but it was later included by Bichsel [27]. The high-energy

behavior of $\delta(\beta\gamma)$ (Eq. (30.6)) is such that

$$\Delta_p \xrightarrow[\beta\gamma\gtrsim 100]{} \xi \left[\ln \frac{2mc^2\xi}{(\hbar\omega_p)^2} + j \right] .$$
(30.12)

Thus the Landau-Vavilov most probable energy loss, like the restricted energy loss, reaches a Fermi plateau. The Bethe dE/dx and Landau-Vavilov-Bichsel Δ_p/x in silicon are shown as a function of muon energy in Fig. 30.6. The energy deposit in the 1600 μ m case is roughly the same as in a 3 mm thick plastic scintillator.

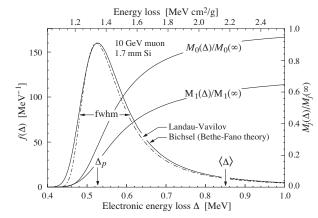

Figure 30.7: Electronic energy deposit distribution for a 10 GeV muon traversing 1.7 mm of silicon, the stopping power equivalent of about 0.3 cm of PVC scintillator [1,13,29]. The Landau-Vavilov function (dot-dashed) uses a Rutherford cross section without atomic binding corrections but with a kinetic energy transfer limit of $T_{\rm max}$. The solid curve was calculated using Bethe-Fano theory. $M_0(\Delta)$ and $M_1(\Delta)$ are the cumulative 0th moment (mean number of collisions) and 1st moment (mean energy loss) in crossing the silicon. (See Sec. 30.2.1. The fwhm of the Landau-Vavilov function is about 4ξ for detectors of moderate thickness. Δ_p is the most probable energy loss, and $\langle \Delta \rangle$ divided by the thickness is the Bethe $\langle dE/dx \rangle$.

The distribution function for the energy deposit by a 10 GeV muon going through a detector of about this thickness is shown in Fig. 30.7. In this case the most probable energy loss is 62\% of the mean $(M_1(\langle \Delta \rangle)/M_1(\infty))$. Folding in experimental resolution displaces the peak of the distribution, usually toward a higher value. 90% of the collisions $(M_1(\langle \Delta \rangle)/M_1(\infty))$ contribute to energy deposits below the mean. It is the very rare high-energytransfer collisions, extending to T_{max} at several GeV, that drives the mean into the tail of the distribution. The mean of the energy loss given by the Bethe equation, Eq. (30.4), is thus ill-defined experimentally and is not useful for describing energy loss by single particles.* It rises as $\ln \beta \gamma$ because $T_{\rm max}$ increases as $\beta^2 \gamma^2$. The large single-collision energy transfers that increasingly extend the long tail are rare, making the mean of an experimental distribution consisting of a few hundred events subject to large fluctuations and sensitive to cuts. The most probable energy loss should be used.

The Landau distribution fails to describe energy loss in thin absorbers such as gas TPC cells [1] and Si detectors [27], as shown clearly in Fig. 1 of Ref. 1 for an argon-filled TPC cell. Also

^{*} $G \lesssim 0.05$ –0.1, where G is given by Rossi [Ref. 2, Eq. 2.7.10]. It is Vavilov's κ [26].

[†] Rossi [2], Talman [28], and others give somewhat different values for j. The most probable loss is not sensitive to its value.

 $^{\ ^*}$ It does find application in do simetry, where only bulk deposit is relevant.

 $^{^{\}dagger}$ An alternative approach is taken in TPC analysis, where some fraction of the highest energy deposit signals along a track, e.g. 20%, are discarded before taking the average.

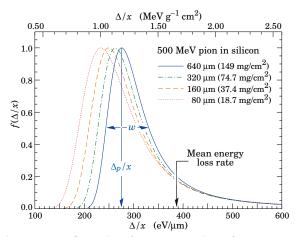

Figure 30.8: Straggling functions in silicon for 500 MeV pions, normalized to unity at the most probable value δ_p/x . The width w is the full width at half maximum.

see Talman [28]. While Δ_p/x may be calculated adequately with Eq. (30.11), the distributions are significantly wider than the Landau width $w=4\xi$ [Ref. 27, Fig. 15]. Examples for 500 MeV pions incident on thin silicon detectors are shown in Fig. 30.8. For very thick absorbers the distribution is less skewed but never approaches a Gaussian.

The most probable energy loss, scaled to the mean loss at minimum ionization, is shown in Fig. 30.9 for several silicon detector thicknesses.

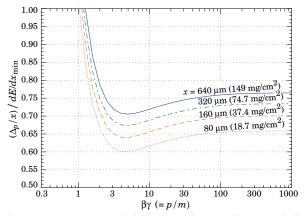

Figure 30.9: Most probable energy loss in silicon, scaled to the mean loss of a minimum ionizing particle, 388 eV/ μ m (1.66 MeV g⁻¹cm²).

30.2.8. Energy loss in mixtures and compounds: A mixture or compound can be thought of as made up of thin layers of pure elements in the right proportion (Bragg additivity). In this case,

$$\frac{dE}{dx} = \sum w_j \left. \frac{dE}{dx} \right|_j \,, \tag{30.13}$$

where $dE/dx|_j$ is the mean rate of energy loss (in MeV g cm⁻²) in the jth element. Eq. (30.4) can be inserted into Eq. (30.13) to find expressions for $\langle Z/A \rangle$, $\langle I \rangle$, and $\langle \delta \rangle$; for example, $\langle Z/A \rangle = \sum w_j Z_j/A_j = \sum n_j Z_j/\sum n_j A_j$. However, $\langle I \rangle$ as defined this way is an underestimate, because in a compound electrons are more tightly bound than in the free elements, and $\langle \delta \rangle$ as calculated this way has little relevance, because it is the electron density that matters. If possible, one uses the tables given in Refs. 21 and 30, which include effective excitation energies and interpolation coefficients for calculating the density effect correction for the chemical elements and nearly 200 mixtures and com-

pounds. If a compound or mixture is not found, then one uses the recipe for δ given in Ref. 22 (repeated in Ref. 5), and calculates $\langle I \rangle$ according to the discussion in Ref. 10. (Note the "13%" rule!)

30.2.9. Ionization yields: Physicists frequently relate total energy loss to the number of ion pairs produced near the particle's track. This relation becomes complicated for relativistic particles due to the wandering of energetic knock-on electrons whose ranges exceed the dimensions of the fiducial volume. For a qualitative appraisal of the nonlocality of energy deposition in various media by such modestly energetic knock-on electrons, see Ref. 31. The mean local energy dissipation per local ion pair produced, W, while essentially constant for relativistic particles, increases at slow particle speeds [32]. For gases, W can be surprisingly sensitive to trace amounts of various contaminants [32]. Furthermore, ionization yields in practical cases may be greatly influenced by such factors as subsequent recombination [33].

30.3. Multiple scattering through small angles

A charged particle traversing a medium is deflected by many small-angle scatters. Most of this deflection is due to Coulomb scattering from nuclei, and hence the effect is called multiple Coulomb scattering. (However, for hadronic projectiles, the strong interactions also contribute to multiple scattering.) The Coulomb scattering distribution is well represented by the theory of Molière [35]. It is roughly Gaussian for small deflection angles, but at larger angles (greater than a few θ_0 , defined below) it behaves like Rutherford scattering, with larger tails than does a Gaussian distribution.

If we define

$$\theta_0 = \theta_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{2}} \theta_{\text{space}}^{\text{rms}}$$
 (30.14)

then it is sufficient for many applications to use a Gaussian approximation for the central 98% of the projected angular distribution, with a width given by [36,37]

$$\theta_0 = \frac{13.6 \text{ MeV}}{\beta cp} z \sqrt{x/X_0} \Big[1 + 0.038 \ln(x/X_0) \Big] . \tag{30.15}$$

Here p, βc , and z are the momentum, velocity, and charge number of the incident particle, and x/X_0 is the thickness of the scattering medium in radiation lengths (defined below). This value of θ_0 is from a fit to Molière distribution for singly charged particles with $\beta=1$ for all Z, and is accurate to 11% or better for $10^{-3} < x/X_0 < 100$.

Eq. (30.15) describes scattering from a single material, while the usual problem involves the multiple scattering of a particle traversing many different layers and mixtures. Since it is from a fit to a Molière distribution, it is incorrect to add the individual θ_0 contributions in quadrature; the result is systematically too small. It is much more accurate to apply Eq. (30.15) once, after finding x and X_0 for the combined scatterer.

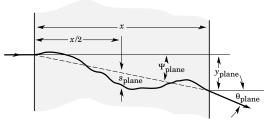

Figure 30.10: Quantities used to describe multiple Coulomb scattering. The particle is incident in the plane of the figure.

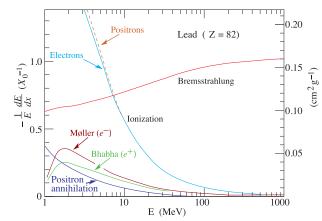

Figure 30.11: Fractional energy loss per radiation length in lead as a function of electron or positron energy. Electron (positron) scattering is considered as ionization when the energy loss per collision is below 0.255 MeV, and as Møller (Bhabha) scattering when it is above. Adapted from Fig. 3.2 from Messel and Crawford, *Electron-Photon Shower Distribution Function Tables for Lead, Copper, and Air Absorbers*, Pergamon Press, 1970. Messel and Crawford use $X_0(\text{Pb}) = 5.82 \text{ g/cm}^2$, but we have modified the figures to reflect the value given in the Table of Atomic and Nuclear Properties of Materials $(X_0(\text{Pb}) = 6.37 \text{ g/cm}^2)$.

The nonprojected (space) and projected (plane) angular distributions are given approximately by [35]

$$\frac{1}{2\pi\,\theta_0^2} \exp\left(-\frac{\theta_{\text{space}}^2}{2\theta_0^2}\right) d\Omega \,, \tag{30.16}$$

$$\frac{1}{\sqrt{2\pi}\,\theta_0} \exp\left(-\frac{\theta_{\text{plane}}^2}{2\theta_0^2}\right) d\theta_{\text{plane}} \,, \tag{30.17}$$

where θ is the deflection angle. In this approximation, $\theta_{\mathrm{space}}^2 \approx (\theta_{\mathrm{plane},x}^2 + \theta_{\mathrm{plane},y}^2)$, where the x and y axes are orthogonal to the direction of motion, and $d\Omega \approx d\theta_{\mathrm{plane},x} \, d\theta_{\mathrm{plane},y}$. Deflections into $\theta_{\mathrm{plane},x}$ and $\theta_{\mathrm{plane},y}$ are independent and identically distributed.

Fig. 30.10 shows these and other quantities sometimes used to describe multiple Coulomb scattering. They are

$$\psi_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} \theta_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} \theta_0 , \qquad (30.18)$$

$$y_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} x \theta_{\text{plane}}^{\text{rms}} = \frac{1}{\sqrt{3}} x \theta_0,$$
 (30.19)

$$s_{\text{plane}}^{\text{rms}} = \frac{1}{4\sqrt{3}} x \theta_{\text{plane}}^{\text{rms}} = \frac{1}{4\sqrt{3}} x \theta_0. \qquad (30.20)$$

All the quantitative estimates in this section apply only in the limit of small $\theta_{\rm plane}^{\rm rms}$ and in the absence of large-angle scatters. The random variables $s,\ \psi,\ y,\$ and θ in a given plane are correlated. Obviously, $y\approx x\psi.$ In addition, y and θ have the correlation coefficient $\rho_{y\theta}=\sqrt{3}/2\approx 0.87.$ For Monte Carlo generation of a joint $(y_{\rm plane},\theta_{\rm plane})$ distribution, or for other calculations, it may be most convenient to work with independent Gaussian random variables (z_1,z_2) with mean zero and variance one, and then set

$$y_{\text{plane}} = z_1 x \theta_0 (1 - \rho_{y\theta}^2)^{1/2} / \sqrt{3} + z_2 \rho_{y\theta} x \theta_0 / \sqrt{3}$$
 (30.21)

$$= z_1 x \theta_0 / \sqrt{12} + z_2 x \theta_0 / 2 ; \qquad (30.22)$$

$$\theta_{\text{plane}} = z_2 \,\theta_0 \,. \tag{30.23}$$

Note that the second term for y_{plane} equals $x \theta_{\text{plane}}/2$ and represents the displacement that would have occurred had the deflection θ_{plane} all occurred at the single point x/2.

For heavy ions the multiple Coulomb scattering has been measured and compared with various theoretical distributions [38].

30.4. Photon and electron interactions in matter

30.4.1. Radiation length: High-energy electrons predominantly lose energy in matter by bremsstrahlung, and high-energy photons by e^+e^- pair production. The characteristic amount of matter traversed for these related interactions is called the radiation length X_0 , usually measured in g cm⁻². It is both (a) the mean distance over which a high-energy electron loses all but 1/e of its energy by bremsstrahlung, and (b) $\frac{7}{9}$ of the mean free path for pair production by a high-energy photon [39]. It is also the appropriate scale length for describing high-energy electromagnetic cascades. X_0 has been calculated and tabulated by Y.S. Tsai [40]:

$$\frac{1}{X_0} = 4\alpha r_e^2 \frac{N_A}{A} \left\{ Z^2 [L_{\rm rad} - f(Z)] + Z L'_{\rm rad} \right\}.$$
 (30.24)

For $A=1~{\rm g~mol^{-1}}$, $4\alpha r_e^2 N_A/A=(716.408~{\rm g~cm^{-2}})^{-1}$. $L_{\rm rad}$ and $L'_{\rm rad}$ are given in Table 30.2. The function f(Z) is an infinite sum, but for elements up to uranium can be represented to 4-place accuracy by

$$f(Z) = a^{2} \left[(1 + a^{2})^{-1} + 0.20206 -0.0369 a^{2} + 0.0083 a^{4} - 0.002 a^{6} \right],$$
 (30.25)

where $a = \alpha Z$ [41].

Table 30.2: Tsai's $L_{\rm rad}$ and $L'_{\rm rad}$, for use in calculating the radiation length in an element using Eq. (30.24).

| Element | Z | L_{rad} | $L'_{ m rad}$ |
|------------------|----|-----------------------|---------------------|
| H | 1 | 5.31 | 6.144 |
| $_{\mathrm{He}}$ | 2 | 4.79 | 5.621 |
| ${ m Li}$ | 3 | 4.74 | 5.805 |
| ${\rm Be}$ | 4 | 4.71 | 5.924 |
| Others | >4 | $\ln(184.15Z^{-1/3})$ | $\ln(1194Z^{-2/3})$ |

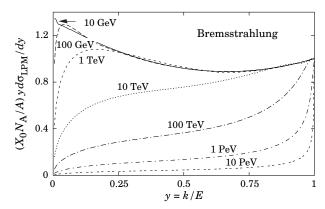

Figure 30.12: The normalized bremsstrahlung cross section $k \, d\sigma_{LPM}/dk$ in lead versus the fractional photon energy y=k/E. The vertical axis has units of photons per radiation length.

The radiation length in a mixture or compound may be approximated by

$$1/X_0 = \sum w_j/X_j , \qquad (30.26)$$

where w_j and X_j are the fraction by weight and the radiation length for the jth element.

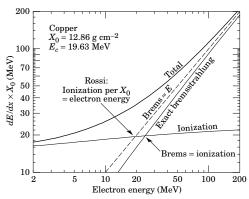

Figure 30.13: Two definitions of the critical energy E_c .

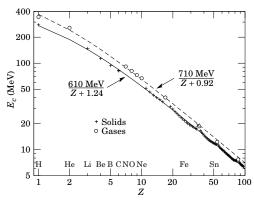

Figure 30.14: Electron critical energy for the chemical elements, using Rossi's definition [2]. The fits shown are for solids and liquids (solid line) and gases (dashed line). The rms deviation is 2.2% for the solids and 4.0% for the gases. (Computed with code supplied by A. Fassó.)

30.4.2. Energy loss by electrons: At low energies electrons and positrons primarily lose energy by ionization, although other processes (Møller scattering, Bhabha scattering, e^+ annihilation) contribute, as shown in Fig. 30.11. While ionization loss rates rise logarithmically with energy, bremsstrahlung losses rise nearly linearly (fractional loss is nearly independent of energy), and dominates above a few tens of MeV in most materials (See Sec. 30.4.3 below.)

Ionization loss by electrons and positrons differ somewhat, and both differ from loss by heavy particles because of the kinematics, spin, and the identity of the incident electron with the electrons which it ionizes. Complete discussions and tables can be found in Refs. 10, 11, and 30.

At very high energies and except at the high-energy tip of the bremsstrahlung spectrum, the cross section can be approximated in the "complete screening case" as [40]

$$d\sigma/dk = (1/k)4\alpha r_e^2 \{ (\frac{4}{3} - \frac{4}{3}y + y^2)[Z^2(L_{\text{rad}} - f(Z)) + ZL'_{\text{rad}}] + \frac{1}{9}(1-y)(Z^2 + Z) \},$$
(30.27)

where y=k/E is the fraction of the electron's energy transfered to the radiated photon. At small y (the "infrared limit") the term on the second line ranges from 1.7% (low Z) to 2.5% (high Z) of the total. If it is ignored and the first line simplified with the definition of X_0 given in Eq. (30.24), we have

$$\frac{d\sigma}{dk} = \frac{A}{X_0 N_A k} \left(\frac{4}{3} - \frac{4}{3} y + y^2\right) . \tag{30.28}$$

This cross section (times k) is shown by the top curve in Fig. 30.12.

This formula is accurate except in near y = 1, where

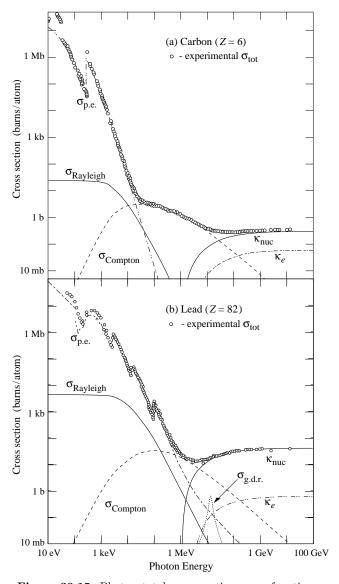

Figure 30.15: Photon total cross sections as a function of energy in carbon and lead, showing the contributions of different processes [48]:

 $\sigma_{\text{p.e.}} = \text{Atomic photoelectric effect (electron ejection, photon absorption)}$

 $\sigma_{\text{Rayleigh}} = \text{Rayleigh (coherent)}$ scattering–atom neither ionized nor excited

 $\sigma_{\text{Compton}} = \text{Incoherent scattering (Compton scattering off an electron)}$

 $\kappa_{\mathrm{nuc}} = \text{Pair production, nuclear field}$

 κ_e = Pair production, electron field

 $\sigma_{\rm g.d.r.}$ = Photonuclear interactions, most notably the Giant Dipole Resonance [49]. In these interactions, the target nucleus is broken up.

Original figures through the courtesy of John H. Hubbell (NIST).

screening may become incomplete, and near y=0, where the infrared divergence is removed by the interference of bremsstrahlung amplitudes from nearby scattering centers (the LPM effect) [42,43] and dielectric suppression [44,45]. These and other suppression effects in bulk media are discussed in Sec. 30.4.5.

With decreasing energy ($E \lesssim 10 \text{ GeV}$) the high-y cross section drops and the curves become rounded as $y \to 1$. Curves of this

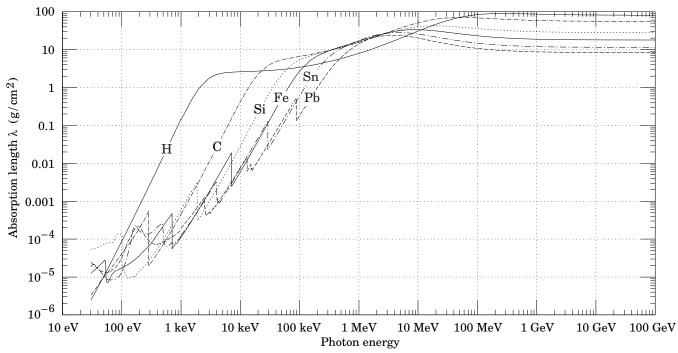

Fig. 30.16: The photon mass attenuation length (or mean free path) $\lambda = 1/(\mu/\rho)$ for various elemental absorbers as a function of photon energy. The mass attenuation coefficient is μ/ρ , where ρ is the density. The intensity I remaining after traversal of thickness t (in mass/unit area) is given by $I = I_0 \exp(-t/\lambda)$. The accuracy is a few percent. For a chemical compound or mixture, $1/\lambda_{\rm eff} \approx \sum_{\rm elements} w_Z/\lambda_Z$, where w_Z is the proportion by weight of the element with atomic number Z. The processes responsible for attenuation are given in Fig. 30.11. Since coherent processes are included, not all these processes result in energy deposition. The data for 30 eV < E < 1 keV are obtained from http://www-cxro.lbl.gov/optical_constants (courtesy of Eric M. Gullikson, LBNL). The data for 1 keV < E < 100 GeV are from http://physics.nist.gov/PhysRefData, through the courtesy of John H. Hubbell (NIST).

familar shape can be seen in Rossi [2] (Figs. 2.11.2,3); see also the review by Koch & Motz [46].

Except at these extremes, and still in the complete-screening approximation, the number of photons with energies between k_{\min} and k_{\max} emitted by an electron travelling a distance $d \ll X_0$ is

$$N_{\gamma} = \frac{d}{X_0} \left[\frac{4}{3} \ln \left(\frac{k_{\text{max}}}{k_{\text{min}}} \right) - \frac{4(k_{\text{max}} - k_{\text{min}})}{3E} + \frac{k_{\text{max}}^2 - k_{\text{min}}^2}{2E^2} \right]. \tag{30.29}$$

30.4.3. Critical energy: An electron loses energy by bremsstrahlung at a rate nearly proportional to its energy, while the ionization loss rate varies only logarithmically with the electron energy. The critical energy E_c is sometimes defined as the energy at which the two loss rates are equal [47]. Among alternate definitions is that of Rossi [2], who defines the critical energy as the energy at which the ionization loss per radiation length is equal to the electron energy. Equivalently, it is the same as the first definition with the approximation $|dE/dx|_{\text{brems}} \approx E/X_0$. This form has been found to describe transverse electromagnetic shower development more accurately (see below). These definitions are illustrated in the case of copper in Fig. 30.13.

The accuracy of approximate forms for E_c has been limited by the failure to distinguish between gases and solid or liquids, where there is a substantial difference in ionization at the relevant energy because of the density effect. We distinguish these two cases in Fig. 30.14. Fits were also made with functions of the form $a/(Z+b)^{\alpha}$, but α was found to be essentially unity. Since E_c also depends on A, I, and other factors, such forms are at best approximate.

Values of E_c for both electrons and positrons in more than 300 materials can be found at pdg.lbl.gov/AtomicNuclearProperties.

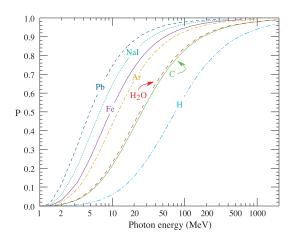

Figure 30.17: Probability P that a photon interaction will result in conversion to an e^+e^- pair. Except for a few-percent contribution from photonuclear absorption around 10 or 20 MeV, essentially all other interactions in this energy range result in Compton scattering off an atomic electron. For a photon attenuation length λ (Fig. 30.16), the probability that a given photon will produce an electron pair (without first Compton scattering) in thickness t of absorber is $P[1 - \exp(-t/\lambda)]$.

30.4.4. Energy loss by photons: Contributions to the photon cross section in a light element (carbon) and a heavy element (lead) are shown in Fig. 30.15. At low energies it is seen that the photoelectric effect dominates, although Compton scattering, Rayleigh scattering, and photonuclear absorption also contribute. The photoelectric cross section is characterized by discontinuities (absorption edges) as thresholds for photoionization of various atomic levels are reached. Photon attenuation lengths for a variety of elements are shown in Fig. 30.16, and data for $30~{\rm eV} < k < 100~{\rm GeV}$ for all elements is available from the web pages given in the caption. Here k is the photon energy.

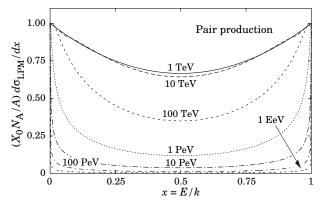

Figure 30.18: The normalized pair production cross section $d\sigma_{LPM}/dy$, versus fractional electron energy x=E/k.

The increasing domination of pair production as the energy increases is shown in Fig. 30.17. Using approximations similar to those used to obtain Eq. (30.28), Tsai's formula for the differential cross section [40] reduces to

$$\frac{d\sigma}{dx} = \frac{A}{X_0 N_A} \left[1 - \frac{4}{3} x (1 - x) \right]$$
 (30.30)

in the complete-screening limit valid at high energies. Here x=E/k is the fractional energy transfer to the pair-produced electron (or positron), and k is the incident photon energy. The cross section is very closely related to that for bremsstrahlung, since the Feynman diagrams are variants of one another. The cross section is of necessity symmetric between x and 1-x, as can be seen by the solid curve in Fig. 30.18. See the review by Motz, Olsen, & Koch for a more detailed treatment [50].

Eq. (30.30) may be integrated to find the high-energy limit for the total e^+e^- pair-production cross section:

$$\sigma = \frac{7}{9}(A/X_0N_A) \ . \tag{30.31}$$

Equation Eq. (30.31) is accurate to within a few percent down to energies as low as 1 GeV, particularly for high-Z materials.

30.4.5. Bremsstrahlung and pair production at very high energies: At ultrahigh energies, Eqns. 30.27–30.31 will fail because of quantum mechanical interference between amplitudes from different scattering centers. Since the longitudinal momentum transfer to a given center is small ($\propto k/E(E-k)$, in the case of bremsstrahlung), the interaction is spread over a comparatively long distance called the formation length ($\propto E(E-k)/k$) via the uncertainty principle. In alternate language, the formation length is the distance over which the highly relativistic electron and the photon "split apart." The interference is usually destructive. Calculations of the "Landau-Pomeranchuk-Migdal" (LPM) effect may be made semi-classically based on the average multiple scattering, or more rigorously using a quantum transport approach [42,43].

In amorphous media, bremsstrahlung is suppressed if the photon energy k is less than $E^2/(E+E_{LPM})$ [43], where*

$$E_{LPM} = \frac{(m_e c^2)^2 \alpha X_0}{4\pi\hbar c\rho} = (7.7 \text{ TeV/cm}) \times \frac{X_0}{\rho} .$$
 (30.32)

Since physical distances are involved, X_0/ρ , in cm, appears. The energy-weighted bremsstrahlung spectrum for lead, $k\,d\sigma_{LPM}/dk$, is shown in Fig. 30.12. With appropriate scaling by X_0/ρ , other materials behave similarly.

For photons, pair production is reduced for $E(k-E) > k E_{LPM}$. The pair-production cross sections for different photon energies are shown in Fig. 30.18.

If $k \ll E$, several additional mechanisms can also produce suppression. When the formation length is long, even weak factors can perturb the interaction. For example, the emitted photon can coherently forward scatter off of the electrons in the media. Because of this, for $k < \omega_p E/m_e \sim 10^{-4}$, bremsstrahlung is suppressed by a factor $(km_e/\omega_p E)^2$ [45]. Magnetic fields can also suppress bremsstrahlung.

In crystalline media, the situation is more complicated, with coherent enhancement or suppression possible. The cross section depends on the electron and photon energies and the angles between the particle direction and the crystalline axes [52].

30.4.6. Photonuclear and electronuclear interactions at still higher energies: At still higher photon and electron energies, where the bremsstrahlung and pair production cross-sections are heavily suppressed by the LPM effect, photonuclear and electronuclear interactions predominate over electromagnetic interactions.

At photon energies above about 10^{20} eV, for example, photons usually interact hadronically. The exact cross-over energy depends on the model used for the photonuclear interactions. At still higher energies ($\gtrsim 10^{23}$ eV), photonuclear interactions can become coherent, with the photon interaction spread over multiple nuclei. Essentially, the photon coherently converts to a ρ^0 , in a process that is somewhat similar to kaon regeneration [53]. These processes are illustrated in Fig. 30.19.

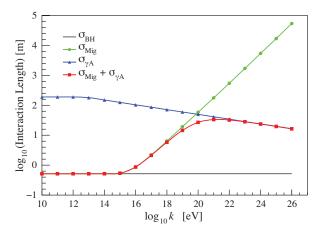

Figure 30.19: Interaction length for a photon in ice as a function of photon energy for the Bethe-Heitler (BH), LPM (Mig) and photonuclear (γA) cross sections [53]. The Bethe-Heitler interaction length is $9X_0/7$, and X_0 is 0.393 m in ice.

Similar processes occur for electrons. As electron energies increase and the LPM effect suppresses bremsstrahlung,

^{*} This definition differs from that of Ref. 51 by a factor of two. E_{LPM} scales as the 4th power of the mass of the incident particle, so that $E_{LPM} = (1.4 \times 10^{10} \text{ TeV/cm}) \times X_0/\rho$ for a muon.

electronuclear interactions become more important. At energies above 10^{21} eV, these electronuclear interactions dominate electron energy loss [53].

30.5. Electromagnetic cascades

When a high-energy electron or photon is incident on a thick absorber, it initiates an electromagnetic cascade as pair production and bremsstrahlung generate more electrons and photons with lower energy. The longitudinal development is governed by the high-energy part of the cascade, and therefore scales as the radiation length in the material. Electron energies eventually fall below the critical energy, and then dissipate their energy by ionization and excitation rather than by the generation of more shower particles. In describing shower behavior, it is therefore convenient to introduce the scale variables

$$t = x/X_0$$
, $y = E/E_c$, (30.33)

so that distance is measured in units of radiation length and energy in units of critical energy.

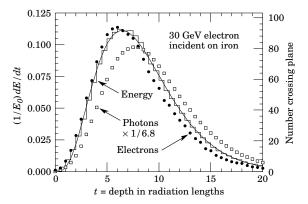

Figure 30.20: An EGS4 simulation of a 30 GeV electroninduced cascade in iron. The histogram shows fractional energy deposition per radiation length, and the curve is a gamma-function fit to the distribution. Circles indicate the number of electrons with total energy greater than 1.5 MeV crossing planes at $X_0/2$ intervals (scale on right) and the squares the number of photons with $E \geq 1.5$ MeV crossing the planes (scaled down to have same area as the electron distribution).

Longitudinal profiles from an EGS4 [54] simulation of a 30 GeV electron-induced cascade in iron are shown in Fig. 30.20. The number of particles crossing a plane (very close to Rossi's Π function [2]) is sensitive to the cutoff energy, here chosen as a total energy of 1.5 MeV for both electrons and photons. The electron number falls off more quickly than energy deposition. This is because, with increasing depth, a larger fraction of the cascade energy is carried by photons. Exactly what a calorimeter measures depends on the device, but it is not likely to be exactly any of the profiles shown. In gas counters it may be very close to the electron number, but in glass Cherenkov detectors and other devices with "thick" sensitive regions it is closer to the energy deposition (total track length). In such detectors the signal is proportional to the "detectable" track length T_d , which is in general less than the total track length T. Practical devices are sensitive to electrons with energy above some detection threshold E_d , and $T_d = T F(E_d/E_c)$. An analytic form for $F(E_d/E_c)$ obtained by Rossi [2] is given by Fabjan [55]; see also Amaldi [56]

The mean longitudinal profile of the energy deposition in an electromagnetic cascade is reasonably well described by a gamma

distribution [57]:

$$\frac{dE}{dt} = E_0 b \frac{(bt)^{a-1} e^{-bt}}{\Gamma(a)}$$
(30.34)

The maximum t_{max} occurs at (a-1)/b. We have made fits to shower profiles in elements ranging from carbon to uranium, at energies from 1 GeV to 100 GeV. The energy deposition profiles are well described by Eq. (30.34) with

$$t_{\text{max}} = (a-1)/b = 1.0 \times (\ln y + C_i), \qquad j = e, \gamma, \quad (30.35)$$

where $C_e=-0.5$ for electron-induced cascades and $C_\gamma=+0.5$ for photon-induced cascades. To use Eq. (30.34), one finds (a-1)/b from Eq. (30.35) and Eq. (30.33), then finds a either by assuming $b\approx 0.5$ or by finding a more accurate value from Fig. 30.21. The results are very similar for the electron number profiles, but there is some dependence on the atomic number of the medium. A similar form for the electron number maximum was obtained by Rossi in the context of his "Approximation B," [2] (see Fabjan's review in Ref. 55), but with $C_e=-1.0$ and $C_\gamma=-0.5$; we regard this as superseded by the EGS4 result.

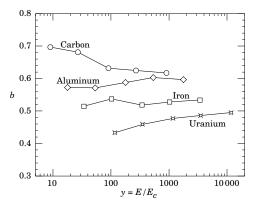

Figure 30.21: Fitted values of the scale factor b for energy deposition profiles obtained with EGS4 for a variety of elements for incident electrons with $1 \le E_0 \le 100$ GeV. Values obtained for incident photons are essentially the same.

The "shower length" $X_s = X_0/b$ is less conveniently parameterized, since b depends upon both Z and incident energy, as shown in Fig. 30.21. As a corollary of this Z dependence, the number of electrons crossing a plane near shower maximum is underestimated using Rossi's approximation for carbon and seriously overestimated for uranium. Essentially the same b values are obtained for incident electrons and photons. For many purposes it is sufficient to take $b \approx 0.5$.

The length of showers initiated by ultra-high energy photons and electrons is somewhat greater than at lower energies since the first or first few interaction lengths are increased via the mechanisms discussed above.

The gamma function distribution is very flat near the origin, while the EGS4 cascade (or a real cascade) increases more rapidly. As a result Eq. (30.34) fails badly for about the first two radiation lengths; it was necessary to exclude this region in making fits.

Because fluctuations are important, Eq. (30.34) should be used only in applications where average behavior is adequate. Grindhammer *et al.* have developed fast simulation algorithms in which the variance and correlation of a and b are obtained by fitting Eq. (30.34) to individually simulated cascades, then generating profiles for cascades using a and b chosen from the correlated distributions [58].

The transverse development of electromagnetic showers in different materials scales fairly accurately with the *Molière radius* R_M , given by [59,60]

$$R_M = X_0 E_s / E_c , (30.36)$$

where $E_s \approx 21$ MeV (Table 30.1), and the Rossi definition of E_c is used.

In a material containing a weight fraction w_j of the element with critical energy E_{cj} and radiation length X_j , the Molière radius is given by

$$\frac{1}{R_M} = \frac{1}{E_s} \sum \frac{w_j E_{cj}}{X_j} \ . \tag{30.37}$$

Measurements of the lateral distribution in electromagnetic cascades are shown in Refs. 59 and 60. On the average, only 10% of the energy lies outside the cylinder with radius R_M . About 99% is contained inside of $3.5R_M$, but at this radius and beyond composition effects become important and the scaling with R_M fails. The distributions are characterized by a narrow core, and broaden as the shower develops. They are often represented as the sum of two Gaussians, and Grindhammer [58] describes them with the function

$$f(r) = \frac{2r\,R^2}{(r^2 + R^2)^2}\;, \tag{30.38}$$

where R is a phenomenological function of x/X_0 and $\ln E$.

At high enough energies, the LPM effect (Sec. 30.4.5) reduces the cross sections for bremsstrahlung and pair production, and hence can cause significant elongation of electromagnetic cascades [43].

30.6. Muon energy loss at high energy

At sufficiently high energies, radiative processes become more important than ionization for all charged particles. For muons and pions in materials such as iron, this "critical energy" occurs at several hundred GeV. (There is no simple scaling with particle mass, but for protons the "critical energy" is much, much higher.) Radiative effects dominate the energy loss of energetic muons found in cosmic rays or produced at the newest accelerators. These processes are characterized by small cross sections, hard spectra, large energy fluctuations, and the associated generation of electromagnetic and (in the case of photonuclear interactions) hadronic showers [61–69]. As a consequence, at these energies the treatment of energy loss as a uniform and continuous process is for many purposes inadequate.

It is convenient to write the average rate of muon energy loss as [70]

$$-dE/dx = a(E) + b(E) E. (30.39)$$

Here a(E) is the ionization energy loss given by Eq. (30.4), and b(E) is the sum of e^+e^- pair production, bremsstrahlung, and photonuclear contributions. To the approximation that these slowly-varying functions are constant, the mean range x_0 of a muon with initial energy E_0 is given by

$$x_0 \approx (1/b) \ln(1 + E_0/E_{\mu c})$$
, (30.40)

where $E_{\mu c} = a/b$. Fig. 30.22 shows contributions to b(E) for iron. Since $a(E) \approx 0.002 \text{ GeV g}^{-1} \text{ cm}^2$, b(E)E dominates the energy loss above several hundred GeV, where b(E) is nearly constant. The rates of energy loss for muons in hydrogen, uranium, and iron are shown in Fig. 30.23 [5].

The "muon critical energy" $E_{\mu c}$ can be defined more exactly as the energy at which radiative and ionization losses are equal, and can be found by solving $E_{\mu c} = a(E_{\mu c})/b(E_{\mu c})$. This definition corresponds to the solid-line intersection in Fig. 30.13, and is different from the Rossi definition we used for electrons. It serves the same function: below $E_{\mu c}$ ionization losses dominate, and above $E_{\mu c}$ radiative effects dominate. The dependence of $E_{\mu c}$ on atomic number Z is shown in Fig. 30.24.

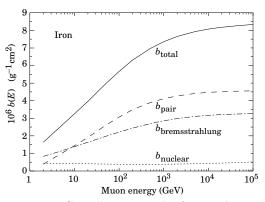

Figure 30.22: Contributions to the fractional energy loss by muons in iron due to e^+e^- pair production, bremsstrahlung, and photonuclear interactions, as obtained from Groom *et al.* [5] except for post-Born corrections to the cross section for direct pair production from atomic electrons.

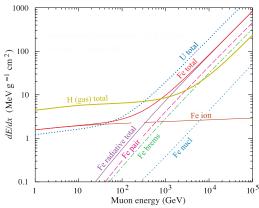

Figure 30.23: The average energy loss of a muon in hydrogen, iron, and uranium as a function of muon energy. Contributions to dE/dx in iron from ionization and the processes shown in Fig. 30.22 are also shown.

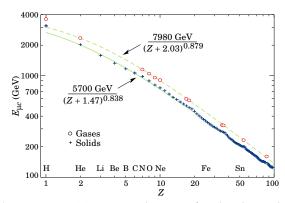

Figure 30.24: Muon critical energy for the chemical elements, defined as the energy at which radiative and ionization energy loss rates are equal [5]. The equality comes at a higher energy for gases than for solids or liquids with the same atomic number because of a smaller density effect reduction of the ionization losses. The fits shown in the figure exclude hydrogen. Alkali metals fall 3–4% above the fitted function, while most other solids are within 2% of the function. Among the gases the worst fit is for radon (2.7% high).

The radiative cross sections are expressed as functions of the fractional energy loss ν . The bremsstrahlung cross section goes roughly as $1/\nu$ over most of the range, while for the pair production case the distribution goes as ν^{-3} to ν^{-2} "Hard" losses are therefore more probable in bremsstrahlung, and in fact energy losses due to pair production may very nearly be treated as continuous. The simulated [69] momentum distribution of an incident 1 TeV/c muon beam after it crosses 3 m of iron is shown in Fig. 30.25. The most probable loss is 8 GeV, or 3.4 MeV $\rm g^{-1}cm^2.$ The full width at half maximum is 9 GeV/c, or 0.9%. The radiative tail is almost entirely due to bremsstrahlung, although most of the events in which more than 10% of the incident energy lost experienced relatively hard photonuclear interactions. The latter can exceed detector resolution [72], necessitating the reconstruction of lost energy. Tables [5] list the stopping power as $9.82 \text{ MeV g}^{-1}\text{cm}^2$ for a 1 TeV muon, so that the mean loss should be 23 GeV ($\approx 23 \text{ GeV}/c$), for a final momentum of 977 GeV/c, far below the peak. This agrees with the indicated mean calculated from the simulation. Electromagnetic and hadronic cascades in detector materials can obscure muon tracks in detector planes and reduce tracking efficiency [73].

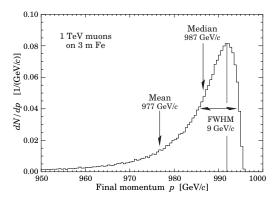

Figure 30.25: The momentum distribution of 1 TeV/c muons after traversing 3 m of iron as calculated with the MARS15 Monte Carlo code [69] by S.I. Striganov [5].

30.7. Cherenkov and transition radiation [74,75,34]

A charged particle radiates if its velocity is greater than the local phase velocity of light (Cherenkov radiation) or if it crosses suddenly from one medium to another with different optical properties (transition radiation). Neither process is important for energy loss, but both are used in high-energy and cosmic-ray physics detectors.

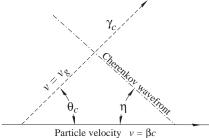

Figure 30.26: Cherenkov light emission and wavefront angles. In a dispersive medium, $\theta_c + \eta \neq 90^0$.

30.7.1. Optical Cherenkov radiation: The angle θ_c of Cherenkov radiation, relative to the particle's direction, for a particle with velocity βc in a medium with index of refraction n is

$$\begin{array}{ll} \cos\theta_c = (1/n\beta) \\ \text{or} & \tan\theta_c = \sqrt{\beta^2 n^2 - 1} \\ & \approx \sqrt{2(1-1/n\beta)} & \text{for small $\theta_c, e.g. in gas} \text{(30.41)} \end{array}$$

The threshold velocity β_t is 1/n, and $\gamma_t = 1/(1-\beta_t^2)^{1/2}$. Therefore, $\beta_t \gamma_t = 1/(2\delta + \delta^2)^{1/2}$, where $\delta = n-1$. Values of δ for various commonly used gases are given as a function of pressure and wavelength in Ref. 76. For values at atmospheric pressure, see Table 6.1. Data for other commonly used materials are given in Ref. 77.

Practical Cherenkov radiator materials are dispersive. Let ω be the photon's frequency, and let $k=2\pi/\lambda$ be its wavenumber. The photons propage at the group velocity $v_g=d\omega/dk=c/[n(\omega)+\omega(dn/d\omega)]$. In a non-dispersive medium, this simplies to $v_g=c/n$.

In his classical paper, Tamm [78] showed that for dispersive media the radiation is concentrated in a thin conical shell whose vertex is at the moving charge, and whose opening half-angle η is given by

$$\cot \eta = \left[\frac{d}{d\omega} (\omega \tan \theta_c) \right]_{\omega_0}$$

$$= \left[\tan \theta_c + \beta^2 \omega \, n(\omega) \, \frac{dn}{d\omega} \cot \theta_c \right]_{\omega_0} , \qquad (30.42)$$

where ω_0 is the central value of the small frequency range under consideration. (See Fig. 30.26.) This cone has a opening half-angle η , and, unless the medium is non-dispersive $(dn/d\omega = 0)$, $\theta_c + \eta \neq 90^0$. The Cherenkov wavefront 'sideslips' along with the particle [79]. This effect may have timing implications for ring imaging Cherenkov counters [80], but it is probably unimportant for most applications.

The number of photons produced per unit path length of a particle with charge ze and per unit energy interval of the photons is

$$\frac{d^2N}{dEdx} = \frac{\alpha z^2}{\hbar c} \sin^2 \theta_c = \frac{\alpha^2 z^2}{r_e m_e c^2} \left(1 - \frac{1}{\beta^2 n^2(E)} \right)$$

$$\approx 370 \sin^2 \theta_c(E) \text{ eV}^{-1} \text{cm}^{-1} \qquad (z = 1) , (30.43)$$

or, equivalently,

$$\frac{d^2N}{dxd\lambda} = \frac{2\pi\alpha z^2}{\lambda^2} \left(1 - \frac{1}{\beta^2 n^2(\lambda)}\right) . \tag{30.44}$$

The index of refraction n is a function of photon energy $E=\hbar\omega$, as is the sensitivity of the transducer used to detect the light. For practical use, Eq. (30.43) must be multiplied by the the transducer response function and integrated over the region for which $\beta\,n(\omega)>1$. Further details are given in the discussion of Cherenkov detectors in the Particle Detectors section (Sec. 31 of this Review).

When two particles are close together (lateral separation $\lesssim 1$ wavelength), the electromagnetic fields from the particles may add coherently, affecting the Cherenkov radiation. Because of their opposite charges, the radiation from an e^+e^- pair at close separation is suppressed compared to two independent leptons [81].

30.7.2. Coherent radio Cherenkov radiation:

Coherent Cherenkov radiation is produced by many charged particles with a non-zero net charge moving through matter on an approximately common "wavefront"—for example, the electrons and positrons in a high-energy electromagnetic cascade. The signals can be visible above backgrounds for shower energies as low as 10^{17} eV; see Sec. 32.3.2 for more details. The

phenomenon is called the Askaryan effect [82]. Near the end of a shower, when typical particle energies are below E_c (but still relativistic), a charge imbalance develops. The photons can Compton-scatter atomic electrons, and positrons can annihilate with atomic electrons to contribute even more photons which can in turn Compton scatter. These processes result in a roughly 20% excess of electrons over positrons in a shower. The net negative charge leads to coherent radio Cherenkov emission. The radiation includes a component from the decellerating charges (as in bremsstrahlung). Because the emission is coherent, the electric field strength is proportional to the shower energy and the signal power increases as its square. The electric field strength also increases linearly with frequency, up to a maximum frequency determined by the lateral spread of the shower. This cutoff occurs at about 1 GHz in ice, and scales inversely with the Moliere radius. At low frequencies, the radiation is roughly isotropic, but, as the frequency rises toward the cutoff frequency, the radiation becomes increasingly peaked around the Cherenkov angle. The radiation is linearly polarized in the plane containing the shower axis and the photon direction. A measurement of the signal polarization can be used to help determine the shower direction. The characteristics of this radiation have been nicely demonstrated in a series of experiments at SLAC [83]. A detailed discussion of the radiation can be found in Ref. 84.

30.7.3. Transition radiation: The energy radiated when a particle with charge ze crosses the boundary between vacuum and a medium with plasma frequency ω_p is

$$I = \alpha z^2 \gamma \hbar \omega_p / 3 , \qquad (30.45)$$

where

$$\hbar\omega_p = \sqrt{4\pi N_e r_e^3} \ m_e c^2/\alpha = \sqrt{\rho \ (\text{in g/cm}^3) \ \langle Z/A \rangle} \times 28.81 \ \text{eV} \ .$$
(30.46)

For styrene and similar materials, $\hbar\omega_p\approx 20$ eV; for air it is 0.7 eV.

The number spectrum $dN_{\gamma}/d(\hbar\omega)$ diverges logarithmically at low energies and decreases rapidly for $\hbar\omega/\gamma\hbar\omega_p>1$. About half the energy is emitted in the range $0.1\leq\hbar\omega/\gamma\hbar\omega_p\leq1$. Inevitable absorption in a practical detector removes the divergence. For a particle with $\gamma=10^3$, the radiated photons are in the soft x-ray range 2 to 40 keV. The γ dependence of the emitted energy thus comes from the hardening of the spectrum rather than from an increased quantum yield.

The number of photons with energy $\hbar\omega > \hbar\omega_0$ is given by the answer to problem 13.15 in Ref. 34,

$$N_{\gamma}(\hbar\omega > \hbar\omega_0) = \frac{\alpha z^2}{\pi} \left[\left(\ln \frac{\gamma \hbar \omega_p}{\hbar\omega_0} - 1 \right)^2 + \frac{\pi^2}{12} \right] , \qquad (30.47)$$

within corrections of order $(\hbar\omega_0/\gamma\hbar\omega_p)^2$. The number of photons above a fixed energy $\hbar\omega_0\ll\gamma\hbar\omega_p$ thus grows as $(\ln\gamma)^2$, but the number above a fixed fraction of $\gamma\hbar\omega_p$ (as in the example above) is constant. For example, for $\hbar\omega>\gamma\hbar\omega_p/10$, $N_\gamma=2.519\,\alpha z^2/\pi=0.59\%\times z^2$.

The particle stays "in phase" with the x ray over a distance called the formation length, $d(\omega)$. Most of the radiation is produced in a distance $d(\omega) = (2c/\omega)(1/\gamma^2 + \theta^2 + \omega_p^2/\omega^2)^{-1}$. Here θ is the x-ray emission angle, characteristically $1/\gamma$. For $\theta = 1/\gamma$ the formation length has a maximum at $d(\gamma\omega_p/\sqrt{2}) = \gamma c/\sqrt{2}\omega_p$. In practical situations it is tens of μ m.

Since the useful x-ray yield from a single interface is low, in practical detectors it is enhanced by using a stack of N foil radiators—foils L thick, where L is typically several formation lengths—separated by gas-filled gaps. The amplitudes at successive interfaces interfere to cause oscillations about the single-interface spectrum. At increasing frequencies above the position of the last interference maximum $(L/d(w) = \pi/2)$, the formation zones, which have opposite phase, overlap more and

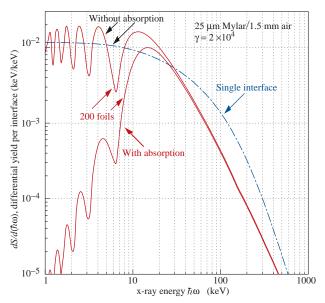

Figure 30.27: X-ray photon energy spectra for a radiator consisting of 200 $25 \,\mu\mathrm{m}$ thick foils of Mylar with 1.5 mm spacing in air (solid lines) and for a single surface (dashed line). Curves are shown with and without absorption. Adapted from Ref. 85.

more and the spectrum saturates, $dI/d\omega$ approaching zero as $L/d(\omega) \rightarrow 0$. This is illustrated in Fig. 30.27 for a realistic detector configuration.

For regular spacing of the layers fairly complicated analytic solutions for the intensity have been obtained [85]. (See also Ref. 86 and references therein.) Although one might expect the intensity of coherent radiation from the stack of foils to be proportional to N^2 , the angular dependence of the formation length conspires to make the intensity $\propto N$.

31.1. Introduction

This review summarizes the detector technologies employed at accelerator particle physics experiments. Several of these detectors are also used in a non-accelerator context and examples of such applications will be provided. The detector techniques which are specific to non-accelerator particle physics experiments are the subject of Chap. 32. More detailed discussions of detectors and their underlying physics can be found in books by Ferbel [1], Kleinknecht [2], Knoll [3], Green [4], Leroy & Rancoita [5], and Grupen [6].

In Table 31.1 are given typical resolutions and deadtimes of common charged particle detectors. The quoted numbers are usually based on typical devices, and should be regarded only as rough approximations for new designs. The spatial resolution refers to the intrinsic detector resolution, i.e. without multiple scattering. We note that analog detector readout can provide better spatial resolution than digital readout by measuring the deposited charge in neighboring channels. Quoted ranges attempt to be representative of both possibilities. The time resolution is defined by how accurately the time at which a particle crossed the detector can be determined. The deadtime is the minimum separation in time between two resolved hits on the same channel. Typical performance of calorimetry and particle identification are provided in the relevant sections below.

Table 31.1: Typical resolutions and deadtimes of common charged particle detectors. Revised November 2011.

| Detector Type | Intrinsinc Spatial Resolution (rms) | | Dead Time |
|-----------------------------|----------------------------------------|------------------------------|-----------------------------|
| Resistive plate chamber | $\lesssim 10 \text{ mm}$ | 1-2 ns | |
| Streamer chamber | $300 \; \mu {\rm m}^{a}$ | $2 \mu s$ | 100 ms |
| Liquid argon drift [7] | ${\sim}175450~\mu\mathrm{m}$ | $\sim 200~\mathrm{ns}$ | $\sim 2~\mu \mathrm{s}$ |
| Scintillation tracker | $\sim 100 \ \mu \mathrm{m}$ | $100 \text{ ps}/n^{b}$ | 10 ns |
| Bubble chamber | $10150~\mu\mathrm{m}$ | 1 ms | 50 ms^c |
| Proportional chamber | $50-100 \ \mu \text{m}^d$ | 2 ns | $20\mbox{-}200~\mathrm{ns}$ |
| Drift chamber | 50–100 $\mu \mathrm{m}$ | 2 ns^e | $20\text{-}100~\mathrm{ns}$ |
| Micro-pattern gas detectors | $3040~\mu\mathrm{m}$ | $<10~\rm ns$ | $10\text{-}100~\mathrm{ns}$ |
| Silicon strip | $pitch/(3 to 7)^f$ | ${\rm few}~{\rm ns}^g$ | $\lesssim 50~\mathrm{ns}^g$ |
| Silicon pixel | $\lesssim 10 \ \mu \mathrm{m}$ | few $\mathbf{n}\mathbf{s}^g$ | $\lesssim 50 \text{ ns}^g$ |
| Emulsion | $1~\mu\mathrm{m}$ | _ | _ |

- ^a 300 μ m is for 1 mm pitch (wirespacing/ $\sqrt{12}$).
- b = n = index of refraction.
- ^c Multiple pulsing time.
- d Delay line cathode readout can give $\pm 150~\mu\mathrm{m}$ parallel to a node wire.
- e For two chambers.
- f The highest resolution ("7") is obtained for small-pitch detectors ($\lesssim \! 25~\mu \mathrm{m})$ with pulse-height-weighted center finding.
- ^g Limited by the readout electronics [8].

31.2. Photon detectors

Updated August 2011 by D. Chakraborty (Northern Illinois U) and T. Sumiyoshi (Tokyo Metro U).

Most detectors in high-energy, nuclear, and astrophysics rely on the detection of photons in or near the visible range, $100\,\mathrm{nm}\lesssim\lambda\lesssim1000\,\mathrm{nm},$ or $E\approx$ a few eV. This range covers scintillation and Cherenkov radiation as well as the light detected in many astronomical observations.

Generally, photodetection involves generating a detectable electrical signal proportional to the (usually very small) number of incident photons. The process involves three distinct steps:

- Generation of a primary photoelectron or electron-hole (e-h) pair by an incident photon by the photoelectric or photoconductive effect,
- Amplification of the p.e. signal to detectable levels by one or more multiplicative bombardment steps and/or an avalanche process (usually), and,

- 3. Collection of the secondary electrons to form the electrical signal.

 The important characteristics of a photodetector include the following in statistical averages:
- 1. Quantum efficiency (QE or ϵ_Q): the number of primary photoelectrons generated per incident photon ($0 \le \epsilon_Q \le 1$; in silicon more than one e-h pair per incident photon can be generated for $\lambda \lesssim 165$ nm),
- 2. Collection efficiency (CE or ϵ_C): the overall acceptance factor other than the generation of photoelectrons ($0 \le \epsilon_C \le 1$),
- Gain (G): the number of electrons collected for each photoelectron generated.
- 4. Dark current or dark noise: the electrical signal when there is no photon,
- 5. Energy resolution: electronic noise (ENC or N_e) and statistical fluctuations in the amplification process compound the Poisson distribution of n_{γ} photons from a given source:

$$\frac{\sigma(E)}{\langle E \rangle} = \sqrt{\frac{f_N}{n_{\gamma} \epsilon_O \epsilon_C} + \left(\frac{N_e}{G n_{\gamma} \epsilon_O \epsilon_C}\right)^2},$$
 (31.1)

where f_N , or the excess noise factor (ENF), is the contribution to the energy distribution variance due to amplification statistics [9],

- 6. Dynamic range: the maximum signal available from the detector (this is usually expressed in units of the response to noise-equivalent power, or NEP, which is the optical input power that produces a signal-to-noise ratio of 1).
- 7. Time dependence of the response: this includes the transit time, which is the time between the arrival of the photon and the electrical pulse, and the transit time spread, which contributes to the pulse rise time and width, and
- Rate capability: inversely proportional to the time needed, after the arrival of one photon, to get ready to receive the next.

requirements, power consumption, calibration needs, aging, cost, and so on. Several technologies employing different phenomena for the three steps described above, and many variants within each, offer a wide range of solutions to choose from. The salient features of the main technologies and the common variants are described below. Some key characteristics are summarized in Table 31.2.

31.2.1. Vacuum photodetectors: Vacuum photodetectors can be broadly subdivided into three types: photomultiplier tubes, microchannel plates, and hybrid photodetectors.

31.2.1.1. Photomultiplier tubes: A versatile class of photon detectors, vacuum photomultiplier tubes (PMT) has been employed by a vast majority of all particle physics experiments to date [9]. Both "transmission-" and "reflection-type" PMT's are widely used. In the former, the photocathode material is deposited on the inside of a transparent window through which the photons enter, while in the latter, the photocathode material rests on a separate surface that the incident photons strike. The cathode material has a low work function, chosen for the wavelength band of interest. When a photon hits the cathode and liberates an electron (the photoelectric effect), the latter is accelerated and guided by electric fields to impinge on a secondary-emission electrode, or dynode, which then emits a few (~ 5) secondary electrons. The multiplication process is repeated typically 10 times in series to generate a sufficient number of electrons, which are collected at the anode for delivery to the external circuit. The total gain of a PMT depends on the applied high voltage V as $G = AV^{kn}$, where $k \approx 0.7-0.8$ (depending on the dynode material), n is the number of dynodes in the chain, and A a constant (which also depends on n). Typically, G is in the range of 10^5 – 10^6 . Pulse risetimes are usually in the few nanosecond range. With e.g. two-level discrimination the effective time resolution can be much better.

Table 31.2: Representative characteristics of some photodetectors commonly used in particle physics. The time resolution of the devices listed here vary in the 10–2000 ps range.

| Туре | λ (nm) | $\epsilon_Q \epsilon_C$ | Gain | Risetime (ns) | Area (mm ²) | 1-p.e noise (Hz) | HV (V) | Price (USD) |

^{*}These devices often come in multi-anode configurations. In such cases, area, noise, and price are to be considered on a "per readout-channel" basis.

The QE is a strong function of the photon wavelength (λ) , and is usually quoted at maximum, together with a range of λ where the QE is comparable to its maximum. Spatial uniformity and linearity with respect to the number of photons are highly desirable in a photodetector's response.

Optimization of these factors involves many trade-offs and vary widely between applications. For example, while a large gain is desirable, attempts to increase the gain for a given device also increases the ENF and after-pulsing ("echos" of the main pulse). In solid-state devices, a higher QE often requires a compromise in the timing properties. In other types, coverage of large areas by focusing increases the transit time spread.

Other important considerations also are highly application-specific. These include the photon flux and wavelength range, the total area to be covered and the efficiency required, the volume available to accommodate the detectors, characteristics of the environment such as chemical composition, temperature, magnetic field, ambient background, as well as ambient radiation of different types and, mode of operation (continuous or triggered), bias (high-voltage)

A large variety of PMT's, including many just recently developed, covers a wide span of wavelength ranges from infrared (IR) to extreme ultraviolet (XUV) [10]. They are categorized by the window materials, photocathode materials, dynode structures, anode configurations, etc. Common window materials are borosilicate glass for IR to near-UV. fused quartz and sapphire (Al₂O₃) for UV, and MgF₂ or LiF for XUV. The choice of photocathode materials include a variety of mostly Csand/or Sb-based compounds such as CsI, CsTe, bi-alkali (SbRbCs, SbKCs), multi-alkali (SbNa₂KCs), GaAs(Cs), GaAsP, etc. Sensitive wavelengths and peak quantum efficiencies for these materials are summarized in Table 31.3. Typical dynode structures used in PMT's are circular cage, line focusing, box and grid, venetian blind, and fine mesh. In some cases, limited spatial resolution can be obtained by using a mosaic of multiple anodes. Fast PMT's with very large windows—measuring up to 508 mm across—have been developed in recent years for detection of Cherenkov radiation in neutrino experiments such as Super-Kamiokande and KamLAND among many others. Specially prepared low-radioactivity glass is used to make these PMT's, and they are also able to withstand the high pressure of the surrounding liquid.

PMT's are vulnerable to magnetic fields—sometimes even the geomagnetic field causes large orientation-dependent gain changes. A high-permeability metal shield is often necessary. However, proximity-focused PMT's, e.g. the fine-mesh types, can be used even in a high magnetic field (≥ 1 T) if the electron drift direction is parallel to the field. CMS uses custom-made vacuum phototriodes (VPT) mounted on the back face of projective lead tungstate crystals to detect scintillation light in the endcap sections of its electromagnetic calorimeters, which are inside a 3.8 T superconducting solenoid. A VPT employs a single dynode (thus, $G \approx 10$) placed close to the photocathode, and a mesh anode plane between the two, to help it cope with the strong magnetic field, which is not too unfavorably oriented with respect to the photodetector axis in the endcaps (within 25°), but where the radiation level is too high for Avalanche Photodiodes (APD's) like those used in the barrel section.

31.2.1.2. Microchannel plates: A typical Microchannel plate (MCP) photodetector consists of one or more ~2 mm thick glass plates with densely packed $O(10 \mu m)$ -diameter cylindrical holes, or "channels", sitting between the transmission-type photocathode and anode planes, separated by O(1 mm) gaps. Instead of discrete dynodes, the inner surface of each cylindrical tube serves as a continuous dynode for the entire cascade of multiplicative bombardments initiated by a photoelectron. Gain fluctuations can be minimized by operating in a saturation mode, whence each channel is only capable of a binary output, but the sum of all channel outputs remains proportional to the number of photons received so long as the photon flux is low enough to ensure that the probability of a single channel receiving more than one photon during a single time gate is negligible. MCP's are thin, offer good spatial resolution, have excellent time resolution ($\sim 20 \text{ ps}$), and can tolerate random magnetic fields up to 0.1 T and axial fields up to ~ 1 T. However, they suffer from relatively long recovery time per channel and short lifetime. MCP's are widely employed as image-intensifiers, although not so much in HEP or astrophysics.

31.2.1.3. Hybrid photon detectors: Hybrid photon detectors (HPD) combine the sensitivity of a vacuum PMT with the excellent spatial and energy resolutions of a Si sensor [11]. A single photoelectron ejected from the photocathode is accelerated through a potential difference of \sim 20 kV before it impinges on the silicon sensor/anode. The gain nearly equals the maximum number of e-h pairs that could be created from the entire kinetic energy of the accelerated electron: $G \approx \text{eV}/w$, where e is the electronic charge, V is the applied potential difference, and $w \approx 3.7 \text{ eV}$ is the mean energy required to create an e-h pair in Si at room temperature. Since the gain is achieved in a single step, one might expect to have the excellent resolution of a simple Poisson statistic with large mean, but in fact it is even better, thanks to the Fano effect discussed in Sec. 31.7.

Low-noise electronics must be used to read out HPD's if one intends to take advantage of the low fluctuations in gain, e.g. when counting small numbers of photons. HPD's can have the same $\epsilon_Q\,\epsilon_C$ and window geometries as PMT's and can be segmented down to $\sim\!50$ $\mu\mathrm{m}$. However, they require rather high biases and will not function in a magnetic field. The exception is proximity-focused devices (\Rightarrow no (de)magnification) in an axial field. With time resolutions of $\sim\!10$ ps and superior rate capability, proximity-focused HPD's can be an alternative to MCP's. Current applications of HPD's include the CMS hadronic calorimeter and the RICH detector in LHCb. Large-size HPD's with sophisticated focusing may be suitable for future water Cherenkov experiments.

Hybrid APD's (HAPD's) add an avalanche multiplication step following the electron bombardment to boost the gain by a factor of ~ 50 . This affords a higher gain and/or lower electrical bias, but also degrades the signal definition.

Table 31.3: Properties of photocathode and window materials commonly used in vacuum photodetectors [10].

| Photocathode material | λ (nm) | Window material | Peak ϵ_Q (λ/nm) |
|--------------------------|----------------|--------------------|---------------------------------------------|
| CsI | 115-200 | MgF_2 | 0.11 (140) |
| CsTe | 115 - 320 | MgF_2 | 0.14(240) |
| Bi-alkali | 300 – 650 | Borosilicate | 0.27(390) |
| | 160 - 650 | Synthetic Silica | 0.27(390) |
| "Ultra Bi-alkali" | 300 – 650 | Borosilicate | 0.43(350) |
| | 160 - 650 | Synthetic Silica | 0.43(350) |
| Multi-alkali | 300 - 850 | Borosilicate | 0.20 (360) |
| | 160-850 | Synthetic Silica | 0.20(360) |
| $GaAs(Cs)^*$ | 160 - 930 | Synthetic Silica | 0.23(280) |
| GaAsP(Cs) | 300 - 750 | Borosilicate | 0.50(500) |
| InP/InGaAsP [†] | 350-1700 | Borosilicate | 0.01 (1100) |

^{*}Reflection type photocathode is used. †Requires cooling to $\sim -80 ^{\circ} \rm C.$

31.2.2. Gaseous photon detectors: In gaseous photomultipliers (GPM) a photoelectron in a suitable gas mixture initiates an avalanche in a high-field region, producing a large number of secondary impactionization electrons. In principle the charge multiplication and collection processes are identical to those employed in gaseous tracking detectors such as multiwire proportional chambers, micromesh gaseous detectors (Micromegas), or gas electron multipliers (GEM). These are discussed in Sec. 31.6.4.

The devices can be divided into two types depending on the photocathode material. One type uses solid photocathode materials much in the same way as PMT's. Since it is resistant to gas mixtures typically used in tracking chambers, CsI is a common choice. In the other type, photoionization occurs on suitable molecules vaporized and mixed in the drift volume. Most gases have photoionization work functions in excess of 10 eV, which would limit their sensitivity to wavelengths far too short. However, vapors of TMAE (tetrakis dimethyl-amine ethylene) or TEA (tri-ethyl-amine), which have smaller work functions (5.3 eV for TMAE and 7.5 eV for TEA), are suited for XUV photon detection [12]. Since devices like GEM's offer sub-mm spatial resolution, GPM's are often used as position-sensitive photon detectors. They can be made into flat panels to cover large areas $(O(1 \text{ m}^2))$, can operate in high magnetic fields, and are relatively inexpensive. Many of the ring imaging Cherenkov (RICH) detectors to date have used GPM's for the detection of Cherenkov light [13]. Special care must be taken to suppress the photon-feedback process in GPM's. It is also important to maintain high purity of the gas as minute traces of O_2 can significantly degrade the detection efficiency.

31.2.3. Solid-state photon detectors: In a phase of rapid development, solid-state photodetectors are competing with vacuum- or gas-based devices for many existing applications and making way for a multitude of new ones. Compared to traditional vacuum- and gaseous photodetectors, solid-state devices are more compact, lightweight, rugged, tolerant to magnetic fields, and often cheaper. They also allow fine pixelization, are easy to integrate into large systems, and can operate at low electric potentials, while matching or exceeding most performance criteria. They are particularly well suited for detection of γ - and X-rays. Except for applications where coverage of very large areas or dynamic range is required, solid-state detectors are proving to be the better choice. Some hybrid devices attempt to combine the best features of different technologies while applications of nanotechnology are opening up exciting new possibilities.

Silicon photodiodes (PD) are widely used in high-energy physics as particle detectors and in a great number of applications (including solar cells!) as light detectors. The structure is discussed in some detail in Sec. 31.7. In its simplest form, the PD is a reverse-biased p-n junction. Photons with energies above the indirect bandgap energy (wavelengths shorter than about 1050 nm, depending on the temperature) can create e-h pairs (the photoconductive effect), which are collected on the p and n sides, respectively. Often, as in the PD's

used for crystal scintillator readout in CLEO, L3, Belle, BaBar, and GLAST, intrinsic silicon is doped to create a p-i-n structure. The reverse bias increases the thickness of the depleted region; in the case of these particular detectors, to full depletion at a depth of about 100 μ m. Increasing the depletion depth decreases the capacitance (and hence electronic noise) and extends the red response. Quantum efficiency can exceed 90%, but falls toward the red because of the increasing absorption length of light in silicon. The absorption length reaches 100 μ m at 985 nm. However, since G=1, amplification is necessary. Optimal low-noise amplifiers are slow, but, even so, noise limits the minimum detectable signal in room-temperature devices to several hundred photons.

Very large arrays containing $O(10^7)$ of $O(10 \ \mu \text{m}^2)$ -sized photodiodes pixelizing a plane are widely used to photograph all sorts of things from everyday subjects at visible wavelengths to crystal structures with X-rays and astronomical objects from infrared to UV. To limit the number of readout channels, these are made into charge-coupled devices (CCD), where pixel-to-pixel signal transfer takes place over thousands of synchronous cycles with sequential output through shift registers [14]. Thus, high spatial resolution is achieved at the expense of speed and timing precision. Custom-made CCD's have virtually replaced photographic plates and other imagers for astronomy and in spacecraft. Typical QE's exceed 90% over much of the visible spectrum, and "thick" CCD's have useful QE up to $\lambda=1~\mu m$. Active Pixel Sensor (APS) arrays with a preamplifier on each pixel and CMOS processing afford higher speeds, but are challenged at longer wavelengths. Much R&D is underway to overcome the limitations of both CCD and CMOS imagers.

In APD's, an exponential cascade of impact ionizations initiated by the original photogenerated e-h pair under a large reverse-bias voltage leads to an avalanche breakdown [15]. As a result, detectable electrical response can be obtained from low-intensity optical signals down to single photons. Excellent junction uniformity is critical, and a guard ring is generally used as a protection against edge breakdown. Well-designed APD's, such as those used in CMS' crystal-based electromagnetic calorimeter, have achieved $\epsilon_Q\,\epsilon_C\approx 0.7$ with sub-ns response time. The sensitive wavelength window and gain depend on the semiconductor used. The gain is typically 10–200 in linear and up to 10^8 in Geiger mode of operation. Stability and close monitoring of the operating temperature are important for linear-mode operation, and substantial cooling is often necessary. Position-sensitive APD's use time information at multiple anodes to calculate the hit position.

One of the most promising recent developments in the field is that of devices consisting of large arrays $(O(10^3))$ of tiny APD's packed over a small area $(O(1 \text{ mm}^2))$ and operated in a limited Geiger mode [16]. Among different names used for this class of photodetectors, "PPD" (for "Pixelized Photon Detector") is most widely accepted (formerly "SiPM"). Although each cell only offers a binary output, linearity with respect to the number of photons is achieved by summing the cell outputs in the same way as with a MCP in saturation mode (see above). PPD's are being adopted as the preferred solution for various purposes including medical imaging, e.g. positron emission tomography (PET). These compact, rugged, and economical devices allow auto-calibration through decent separation of photoelectron peaks and offer gains of $O(10^6)$ at a moderate bias voltage ($\sim 50 \text{ V}$). However, the single-photoelectron noise of a PPD, being the logical "or" of $O(10^3)$ Geiger APD's, is rather large: $O(1 \text{ MHz/mm}^2)$ at room temperature. PPD's are particularly well-suited for applications where triggered pulses of several photons are expected over a small area, e.g. fiber-guided scintillation light. Intense R&D is expected to lower the noise level and improve radiation hardness, resulting in coverage of larger areas and wider applications. Attempts are being made to combine the fabrication of the sensors and the front-end electronics (ASIC) in the same process with the goal of making PPD's and other finely pixelized solid-state photodetectors extremely easy to

Of late, much R&D has been directed to p-i-n diode arrays based on thin polycrystalline diamond films formed by chemical vapor deposition (CVD) on a hot substrate (~ 1000 K) from a hydrocarbon-containing gas mixture under low pressure (~ 100 mbar). These devices have maximum sensitivity in the extreme- to moderate-UV

region [17]. Many desirable characteristics, including high tolerance to radiation and temperature fluctuations, low dark noise, blindness to most of the solar radiation spectrum, and relatively low cost make them ideal for space-based UV/XUV astronomy, measurement of synchrotron radiation, and luminosity monitoring at (future) lepton collider(s).

Visible-light photon counters (VLPC) utilize the formation of an impurity band only 50 meV below the conduction band in As-doped Si to generate strong ($G\approx 5\times 10^4$) yet sharp response to single photons with $\epsilon_Q\approx 0.9$ [18]. The smallness of the band gap considerably reduces the gain dispersion. Only a very small bias (~ 7 V) is needed, but high sensitivity to infrared photons requires cooling below 10 K. The dark noise increases sharply and exponentially with both temperature and bias. The Run 2 DØ detector used 86000 VLPC's to read the optical signal from its scintillating-fiber tracker and scintillator-strip preshower detectors.

31.3. Organic scintillators

Revised August 2011 by Kurtis F. Johnson (FSU).

Organic scintillators are broadly classed into three types, crystalline, liquid, and plastic, all of which utilize the ionization produced by charged particles (see Sec. 30.2 of this Review) to generate optical photons, usually in the blue to green wavelength regions [19]. Plastic scintillators are by far the most widely used, liquid organic scintillator is finding increased use, and crystal organic scintillators are practically unused in high-energy physics. Plastic scintillator densities range from 1.03 to 1.20 g cm $^{-3}$. Typical photon yields are about 1 photon per 100 eV of energy deposit [20]. A one-cm-thick scintillator traversed by a minimum-ionizing particle will therefore yield $\approx 2\times 10^4$ photons. The resulting photoelectron signal will depend on the collection and transport efficiency of the optical package and the quantum efficiency of the photodetector.

Organic scintillator does not respond linearly to the ionization density. Very dense ionization columns emit less light than expected on the basis of dE/dx for minimum-ionizing particles. A widely used semi-empirical model by Birks posits that recombination and quenching effects between the excited molecules reduce the light yield [21]. These effects are more pronounced the greater the density of the excited molecules. Birks' formula is

$$\frac{d\mathcal{L}}{dx} = \mathcal{L}_0 \frac{dE/dx}{1 + k_B dE/dx} , \qquad (31.2)$$

where \mathscr{L} is the luminescence, \mathscr{L}_0 is the luminescence at low specific ionization density, and k_B is Birks' constant, which must be determined for each scintillator by measurement. Decay times are in the ns range; rise times are much faster. The high light yield and fast response time allow the possibility of sub-ns timing resolution [22]. The fraction of light emitted during the decay "tail" can depend on the exciting particle. This allows pulse shape discrimination as a technique to carry out particle identification. Because of the hydrogen content (carbon to hydrogen ratio ≈ 1) plastic scintillator is sensitive to proton recoils from neutrons. Ease of fabrication into desired shapes and low cost has made plastic scintillator a common detector element. In the form of scintillating fiber it has found widespread use in tracking and calorimetry [23].

Demand for large volume detectors has lead to increased use of liquid organic scintillator, which has the same scintillation mechanism as plastic scintillator, due to its cost advantage. The containment vessel defines the detector shape; photodetectors or waveshifters may be immersed in the liquid.

31.3.1. Scintillation mechanism:

A charged particle traversing matter leaves behind it a wake of excited molecules. Certain types of molecules, however, will release a small fraction ($\approx 3\%$) of this energy as optical photons. This process, scintillation, is especially marked in those organic substances which contain aromatic rings, such as polystyrene (PS) and polyvinyltoluene (PVT). Liquids which scintillate include toluene, xylene and pseudocumene.

In fluorescence, the initial excitation takes place via the absorption of a photon, and de-excitation by emission of a longer wavelength photon. Fluors are used as "waveshifters" to shift scintillation light to a more convenient wavelength. Occurring in complex molecules, the absorption and emission are spread out over a wide band of photon energies, and have some overlap, that is, there is some fraction of the emitted light which can be re-absorbed [24]. This "self-absorption" is undesirable for detector applications because it causes a shortened attenuation length. The wavelength difference between the major absorption and emission peaks is called the Stokes shift. It is usually the case that the greater the Stokes shift, the smaller the self absorption thus, a large Stokes shift is a desirable property for a fluor.

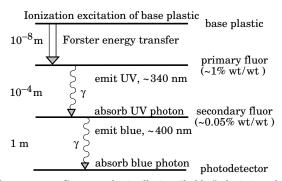

Figure 31.1: Cartoon of scintillation "ladder" depicting the operating mechanism of organic scintillator. Approximate fluor concentrations and energy transfer distances for the separate sub-processes are shown.

The plastic scintillators used in high-energy physics are binary or ternary solutions of selected fluors in a plastic base containing aromatic rings. (See the appendix in Ref. 25 for a comprehensive list of components.) Virtually all plastic scintillators contain as a base either PVT or PS. PVT-based scintillator can be up to 50% brighter.

Ionization in the plastic base produces UV photons with short attenuation length (several mm). Longer attenuation lengths are obtained by dissolving a "primary" fluor in high concentration (1% by weight) into the base, which is selected to efficiently re-radiate absorbed energy at wavelengths where the base is more transparent (see Fig. 31.1).

The primary fluor has a second important function. The decay time of the scintillator base material can be quite long – in pure polystyrene it is 16 ns, for example. The addition of the primary fluor in high concentration can shorten the decay time by an order of magnitude and increase the total light yield. At the concentrations used (1% and greater), the average distance between a fluor molecule and an excited base unit is around 100 Å, much less than a wavelength of light. At these distances the predominant mode of energy transfer from base to fluor is not the radiation of a photon, but a resonant dipole-dipole interaction, first described by Foerster, which strongly couples the base and fluor [26]. The strong coupling sharply increases the speed and the light yield of the plastic scintillators.

Unfortunately, a fluor which fulfills other requirements is usually not completely adequate with respect to emission wavelength or attenuation length, so it is necessary to add yet another waveshifter (the "secondary" fluor), at fractional percent levels, and occasionally a third (not shown in Fig. 31.1).

External wavelength shifters are widely used to aid light collection in complex geometries. Scintillation light is captured by a lightpipe

comprising a wave-shifting fluor dissolved in a nonscintillating base. The wavelength shifter must be insensitive to ionizing radiation and Cherenkov light. A typical wavelength shifter uses an acrylic base because of its good optical qualities, a single fluor to shift the light emerging from the plastic scintillator to the blue-green, and contains ultra-violet absorbing additives to deaden response to Cherenkov light.

31.3.2. Caveats and cautions:

Plastic scintillators are reliable, robust, and convenient. However, they possess quirks to which the experimenter must be alert. Exposure to solvent vapors, high temperatures, mechanical flexing, irradiation, or rough handling will aggravate the process. A particularly fragile region is the surface which can "craze" develop microcracks which degrade its transmission of light by total internal reflection. Crazing is particularly likely where oils, solvents, or *fingerprints* have contacted the surface.

They have a long-lived luminescence which does not follow a simple exponential decay. Intensities at the 10^{-4} level of the initial fluorescence can persist for hundreds of ns [19,27].

They will decrease their light yield with increasing partial pressure of oxygen. This can be a 10% effect in an artificial atmosphere [28]. It is not excluded that other gases may have similar quenching effects.

Their light yield may be changed by a magnetic field. The effect is very nonlinear and apparently not all types of plastic scintillators are so affected. Increases of $\approx 3\%$ at 0.45 T have been reported [29]. Data are sketchy and mechanisms are not understood.

Irradiation of plastic scintillators creates color centers which absorb light more strongly in the UV and blue than at longer wavelengths. This poorly understood effect appears as a reduction both of light yield and attenuation length. Radiation damage depends not only on the integrated dose, but on the dose rate, atmosphere, and temperature, before, during and after irradiation, as well as the materials properties of the base such as glass transition temperature, polymer chain length, etc. Annealing also occurs, accelerated by the diffusion of atmospheric oxygen and elevated temperatures. The phenomena are complex, unpredictable, and not well understood [30]. Since color centers are less disruptive at longer wavelengths, the most reliable method of mitigating radiation damage is to shift emissions at every step to the longest practical wavelengths, e.g., utilize fluors with large Stokes shifts (aka the "Better red than dead" strategy).

31.3.3. Scintillating and wavelength-shifting fibers:

The clad optical fiber comprising scintillator and wavelength shifter (WLS) is particularly useful [31]. Since the initial demonstration of the scintillating fiber (SCIFI) calorimeter [32], SCIFI techniques have become mainstream [33]. SCIFI calorimeters are fast, dense, radiation hard, and can have leadglass-like resolution. SCIFI trackers can handle high rates and are radiation tolerant, but the low photon yield at the end of a long fiber (see below) forces the use of sensitive photodetectors. WLS scintillator readout of a calorimeter allows a very high level of hermeticity since the solid angle blocked by the fiber on its way to the photodetector is very small. The sensitive region of scintillating fibers can be controlled by splicing them onto clear (non-scintillating/non-WLS) fibers.

A typical configuration would be fibers with a core of polystyrenebased scintillator or WLS (index of refraction n = 1.59), surrounded by a cladding of PMMA (n = 1.49) a few microns thick, or, for added light capture, with another cladding of fluorinated PMMA with n = 1.42, for an overall diameter of 0.5 to 1 mm. The fiber is drawn from a boule and great care is taken during production to ensure that the intersurface between the core and the cladding has the highest possible uniformity and quality, so that the signal transmission via total internal reflection has a low loss. The fraction of generated light which is transported down the optical pipe is denoted the capture fraction and is about 6% for the single-clad fiber and 10% for the double-clad fiber. The number of photons from the fiber available at the photodetector is always smaller than desired, and increasing the light yield has proven difficult. A minimum-ionizing particle traversing a high-quality 1 mm diameter fiber perpendicular to its axis will produce fewer than 2000 photons, of which about 200 are captured. Attenuation may eliminate 95% of these photons in a large collider

A scintillating or WLS fiber is often characterized by its attenuation

length, over which the signal is attenuated to 1/e of its original value. Many factors determine the attenuation length, including the importance of re-absorption of emitted photons by the polymer base or dissolved fluors, the level of crystallinity of the base polymer, and the quality of the total internal reflection boundary [34]. Attenuation lengths of several meters are obtained by high quality fibers. However, it should be understood that the attenuation length is not the sole measure of fiber quality. Among other things, it is not constant with distance from the excitation source and it is wavelength dependent.

31.4. Inorganic scintillators:

Revised September 2009 by R.-Y. Zhu (California Institute of Technology) and C.L. Woody (BNL).

Inorganic crystals form a class of scintillating materials with much higher densities than organic plastic scintillators (typically $\sim 4\text{--}8~\text{g/cm}^3)$ with a variety of different properties for use as scintillation detectors. Due to their high density and high effective atomic number, they can be used in applications where high stopping power or a high conversion efficiency for electrons or photons is required. These include total absorption electromagnetic calorimeters (see Sec. 31.9.1), which consist of a totally active absorber (as opposed to a sampling calorimeter), as well as serving as gamma ray detectors over a wide range of energies. Many of these crystals also have very high light output, and can therefore provide excellent energy resolution down to very low energies (\sim few hundred keV).

Some crystals are intrinsic scintillators in which the luminescence is produced by a part of the crystal lattice itself. However, other crystals require the addition of a dopant, typically fluorescent ions such as thallium (Tl) or cerium (Ce) which is responsible for producing the scintillation light. However, in both cases, the scintillation mechanism is the same. Energy is deposited in the crystal by ionization, either directly by charged particles, or by the conversion of photons into electrons or positrons which subsequently produce ionization. This energy is transferred to the luminescent centers which then radiate scintillation photons. The efficiency η for the conversion of energy deposit in the crystal to scintillation light can be expressed by the relation [35]

$$\eta = \beta \cdot S \cdot Q \ . \tag{31.3}$$

where β is the efficiency of the energy conversion process, S is the efficiency of energy transfer to the luminescent center, and Q is the quantum efficiency of the luminescent center. The value of η ranges between 0.1 and \sim 1 depending on the crystal, and is the main factor in determining the intrinsic light output of the scintillator. In addition, the scintillation decay time is primarily determined by the energy transfer and emission process. The decay time of the scintillator is mainly dominated by the decay time of the luminescent center. For example, in the case of thallium doped sodium iodide (NaI(Tl)), the value of η is \sim 0.5, which results in a light output \sim 40,000 photons per MeV of energy deposit. This high light output is largely due to the high quantum efficiency of the thallium ion (Q \sim 1), but the decay time is rather slow ($\tau \sim$ 250 ns).

Table 31.4 lists the basic properties of some commonly used inorganic crystal scintillators. NaI(Tl) is one of the most common and widely used scintillators, with an emission that is well matched to a bialkali photomultiplier tube, but it is highly hygroscopic and difficult to work with, and has a rather low density. CsI(Tl) has high light yield, an emission that is well matched to solid state photodiodes, and is mechanically robust (high plasticity and resistance to cracking). However, it needs careful surface treatment and is slightly hygroscopic. Compared with CsI(Tl), pure CsI has identical mechanical properties, but faster emission at shorter wavelengths and light output approximately an order of magnitude lower. BaF2 has a fast component with a sub-nanosecond decay time, and is the fastest known scintillator. However, it also has a slow component with a much longer decay time (~ 630 ns). Bismuth gemanate (Bi₄Ge₃O₁₂ or BGO) has a high density, and consequently a short radiation length X_0 and Molière radius R_M . BGO's emission is well-matched to the spectral sensitivity of photodiodes, and it is easy to handle and not hygroscopic. Lead tungstate (PbWO₄ or PWO) has a very high density, with a very short X_0 and R_M , but its intrinsic light yield is rather low.

Cerium doped lutetium oxyorthosilicate (Lu_2SiO_5 :Ce, or LSO:Ce) [36] and cerium doped lutetium-yttrium oxyorthosilicate ($\text{Lu}_{2(1-x)}\text{Y}_{2x}\text{SiO}_5$, LYSO:Ce) [37] are dense crystal scintillators which have a high light yield and a fast decay time. Only properties of LSO:Ce is listed in Table 31.4 since the properties of LYSO:Ce are similar to that of LSO:Ce except a little lower density than LSO:Ce depending on the yttrium fraction in LYSO:Ce. This material is also featured with excellent radiation hardness [38], so is expected to be used where extraordinary radiation hardness is required.

Table 31.4 also includes cerium doped lanthanum tri-halides, such as LaBr₃ [39], which is brighter and faster than LSO:Ce, but it is highly hygroscopic and has a lower density. The FWHM energy resolution measured for this material coupled to a PMT with bi-alkali photocathode for 0.662 MeV γ -rays from a ^{137}Cs source is about 3%, which is the best among all inorganic crystal scintillators. For this reason, LaBr₃ is expected to be widely used in applications where a good energy resolution for low energy photons are required, such as homeland security.

Beside the crystals listed in Table 31.4, a number of new crystals are being developed that may have potential applications in high energy or nuclear physics. Of particular interest is the family of yttrium and lutetium perovskites, which include YAP (YAlO3:Ce) and LuAP (LuAlO3:Ce) and their mixed compositions. These have been shown to be linear over a large energy range [40], and have the potential for providing extremely good intrinsic energy resolution. In addition, other fluoride crystals such as ${\rm CeF_3}$ have been shown to provide excellent energy resolution in calorimeter applications.

Aiming at the best jet-mass resolution inorganic scintillators are being investigated for HEP calorimeters with dual readout for both Cherenkov and scintillation light to be used at future linear colliders. These materials may be used for an electromagnetic calorimeter [41] or a homogeneous hadronic calorimetry (HHCAL) detector concept, including both electromagnetic and hadronic parts [42]. Because of the unprecedented volume (70 to 100 m³) foreseen for the HHCAL detector concept the materials must be (1) dense (to minimize the leakage) and (2) cost-effective. It should also be UV transparent (for effective collection of the Cherenkov light) and allow for a clear discrimination between the Cherenkov and scintillation light. The preferred scintillation light is thus at a longer wavelength, and not necessarily bright or fast. Dense crystals, scintillating glasses and ceramics offer a very attractive implementation for this detector concept. Inorganic crystals being investigated are lead fluoride (PbF₂), lead chroride fluoride (PbFCl) and BSO [43].

Table 31.4 gives the light output of other crystals relative to NaI(Tl) and their dependence to the temperature variations measured for crystal samples of 1.5 X_0 cube with a Tyvek paper wrapping and a full end face coupled to a photodetector [44]. The quantum efficiencies of the photodetector is taken out to facilitate a direct comparison of crystal's light output. However, the useful signal produced by a scintillator is usually quoted in terms of the number of photoelectrons per MeV produced by a given photodetector. The relationship between the number of photons/MeV produced and photoelectrons/MeV detected involves the factors for the light collection efficiency L and the quantum efficiency QE of the photodetector:

$$N_{\text{p.e.}}/\text{MeV} = L \cdot QE \cdot N_{\gamma}/\text{MeV}$$
 (31.4)

L includes the transmission of scintillation light within the crystal (i.e., the bulk attenuation length of the material), reflections and scattering from the surfaces, and the size and shape of the crystal. These factors can vary considerably depending on the sample, but can be in the range of $\sim 10-60\%$. The internal light transmission depends on the intrinsic properties of the material, e.g. the density and type of the scattering centers and defects that can produce internal absorption within the crystal, and can be highly affected by factors such as radiation damage, as discussed below.

The quantum efficiency depends on the type of photodetector used to detect the scintillation light, which is typically ${\sim}15{-}20\%$ for photomultiplier tubes and ${\sim}70\%$ for silicon photodiodes for visible wavelengths. The quantum efficiency of the detector is usually highly wavelength dependent and should be matched to the particular crystal of interest to give the highest quantum yield at the wavelength

corresponding to the peak of the scintillation emission. Fig. 31.2 shows the quantum efficiencies of two photodetectors, a Hamamatsu R2059 PMT with bi-alkali cathode and quartz window and a Hamamatsu S8664 avalanche photodiode (APD) as a function of wavelength. Also shown in the figure are emission spectra of three crystal scintillators, BGO, LSO:Ce/LYSO:Ce and CsI(Tl), and the numerical values of the emission weighted quantum efficiency. The area under each emission spectrum is proportional to crystal's light yield, as shown in Table 31.4, where the quantum efficiencies of the photodetector has been taken out. Results with different photodetectors can be significantly different. For example, the response of CsI(Tl) relative to NaI(Tl) with a standard photomultiplier tube with a bi-alkali photo-cathode, e.g. Hamamatsu R2059, would be 45 rather than 165 because of the photomultiplier's low quantum efficiency at longer wavelengths. For scintillators which emit in the UV, a detector with a quartz window should be used.

For very low energy applications (typically below 1 MeV), nonproportionality of the scintillation light yield may be important. It has been known for a long time that the conversion factor between the energy deposited in a crystal scintillator and the number of photons produced is not constant. It is also known that the energy resolution measured by all crystal scintillators for low energy γ -rays is significantly worse than the contribution from photo-electron statistics alone, indicating an intrinsic contribution from the scintillator itself. Precision measurement using low energy electron beam shows that this non-proportionality is crystal dependent [45]. Recent study on this issue also shows that this effect is also sample dependent even for the same crystal [46]. Further work is therefore needed to fully understand this subject.

One important issue related to the application of a crystal scintillator is its radiation hardness. Stability of its light output, or the ability to track and monitor the variation of its light output in a radiation environment, is required for high resolution and precision calibration [47]. All known crystal scintillators suffer from radiation damage. A common damage phenomenon is the appearance of radiation induced absorption caused by the formation of color centers originated from the impurities or point defects in the crystal. This radiation induced absorption reduces the light attenuation length in the crystal, and hence its light output. For crystals with high defect density, a severe reduction of light attenuation length may cause a distortion of the light response uniformity, leading to a degradation of the energy resolution. Additional radiation damage effects may include a reduced intrinsic scintillation light yield (damage to the luminescent centers) and an increased phosphorescence (afterglow). For crystals to be used in the construction a high precision calorimeter in a radiation environment, its scintillation mechanism must not be damaged and its light attenuation length in the expected radiation environment must be long enough so that its light response uniformity, and thus its energy resolution, does not change [48].

Most of the crystals listed in Table 31.4 have been used in high energy or nuclear physics experiments when the ultimate energy resolution for electrons and photons is desired. Examples are the Crystal Ball NaI(Tl) calorimeter at SPEAR, the L3 BGO calorimeter at LEP, the CLEO CsI(Tl) calorimeter at CESR, the KTeV CsI calorimeter at the Tevatron, the BaBar, BELLE and BES II CsI(Tl) calorimeters at PEP-II, KEK and BEPC III. Because of its high density and relative low cost, PWO calorimeters are widely used by CMS and ALICE at LHC, by CLAS and PrimEx at CEBAF, and by PANDA at GSI. Recently, investigations have been made aiming at using LSO:Ce or LYSO:Ce crystals for future high energy or nuclear physics experiments [38].

31.5. Cherenkov detectors

Revised September 2009 by B.N. Ratcliff (SLAC).

Although devices using Cherenkov radiation are often thought of as only particle identification (PID) detectors, in practice they are used over a broader range of applications including; (1) fast particle counters; (2) hadronic PID; and (3) tracking detectors performing complete event reconstruction. Examples of applications from each category include; (1) the BaBar luminosity detector [49]; (2) the hadronic PID detectors at the B factory detectors—DIRC in BaBar [50] and the aerogel threshold Cherenkov in Belle [51]; and (3) large water Cherenkov counters such as Super-Kamiokande [53]. Cherenkov counters contain two main elements; (1) a radiator through which the charged particle passes, and (2) a photodetector. As Cherenkov radiation is a weak source of photons, light collection and detection must be as efficient as possible. The refractive index n and the particle's path length through the radiator L appear in the Cherenkov relations allowing the tuning of these quantities for particular applications.

Cherenkov detectors utilize one or more of the properties of Cherenkov radiation discussed in the Passages of Particles through Matter section (Sec. 30 of this Review): the prompt emission of a light pulse; the existence of a velocity threshold for radiation; and the dependence of the Cherenkov cone half-angle θ_c and the number of emitted photons on the velocity of the particle and the refractive index of the medium.

The number of photoelectrons $(N_{\rm p.e.})$ detected in a given device is

$$N_{\rm p.e.} = L \frac{\alpha^2 z^2}{r_e \, m_e c^2} \int \epsilon(E) \, \sin^2 \theta_c(E) dE , \qquad (31.5)$$

where $\epsilon(E)$ is the efficiency for collecting the Cherenkov light and transducing it into photoelectrons, and $\alpha^2/(r_e m_e c^2) = 370 \text{ cm}^{-1} \text{eV}^{-1}$.

The quantities ϵ and θ_c are functions of the photon energy E. As the typical energy dependent variation of the index of refraction is modest, a quantity called the *Cherenkov detector quality factor* N_0 can be defined as

$$N_0 = \frac{\alpha^2 z^2}{r_e \, m_e c^2} \int \epsilon \, dE \,, \tag{31.6}$$

so that, taking z = 1 (the usual case in high-energy physics),

$$N_{\rm p.e.} \approx L N_0 \langle \sin^2 \theta_c \rangle$$
 (31.7)

This definition of the quality factor N_0 is not universal, nor, indeed, very useful for those common situations where ϵ factorizes as $\epsilon = \epsilon_{\rm coll} \epsilon_{\rm det}$ with the geometrical photon collection efficiency ($\epsilon_{\rm coll}$) varying substantially for different tracks while the photon detector efficiency (ϵ_{det}) remains nearly track independent. In this case, it can be useful to explicitly remove (ϵ_{coll}) from the definition of N_0 . A typical value of N_0 for a photomultiplier (PMT) detection system working in the visible and near UV, and collecting most of the Cherenkov light, is about 100 cm⁻¹. Practical counters, utilizing a variety of different photodetectors, have values ranging between about 30 and 180 cm⁻¹. Radiators can be chosen from a variety of transparent materials (Sec. 30 of this Review and Table 6.1). In addition to refractive index, the choice requires consideration of factors such as material density, radiation length and radiation hardness, transmission bandwidth, absorption length, chromatic dispersion, optical workability (for solids), availability, and cost. When the momenta of particles to be identified is high, the refractive index must be set close to one, so that the photon yield per unit length is low and a long particle path in the radiator is required. Recently, the gap in refractive index that has traditionally existed between gases and liquid or solid materials has been partially closed with transparent silica aerogels with indices that range between about 1.007 and 1.13.

Cherenkov counters may be classified as either *imaging* or *threshold* types, depending on whether they do or do not make use of Cherenkov angle (θ_c) information. Imaging counters may be used to track particles as well as identify them. The recent development of very fast photodetectors such as micro-channel plate PMTs (MCP PMT) (see Sec. 31.2 of this *Review*) also potentially allows very fast Cherenkov based time of flight (TOF) detectors of either class [57].

Threshold Cherenkov detectors [54], in their simplest form, make a yes/no decision based on whether the particle is above or below the Cherenkov threshold velocity $\beta_t = 1/n$. A straightforward enhancement of such detectors uses the number of observed photoelectrons (or a calibrated pulse height) to discriminate between species or to set probabilities for each particle species [55]. This strategy can increase the momentum range of particle separation by a modest amount (to a momentum some 20% above the threshold momentum of the heavier particle in a typical case).

Careful designs give $\langle \epsilon_{\rm coll} \rangle \gtrsim 90\%$. For a photomultiplier with a typical bialkali cathode, $\int \epsilon_{\rm det} dE \approx 0.27$ eV, so that

$$N_{\rm p.e.}/L \approx 90 \text{ cm}^{-1} \langle \sin^2 \theta_c \rangle$$
 (i.e., $N_0 = 90 \text{ cm}^{-1}$). (31.8)

Suppose, for example, that n is chosen so that the threshold for species a is p_t ; that is, at this momentum species a has velocity $\beta_a=1/n$. A second, lighter, species b with the same momentum has velocity β_b , so $\cos\theta_c=\beta_a/\beta_b$, and

$$N_{\text{p.e.}}/L \approx 90 \text{ cm}^{-1} \frac{m_a^2 - m_b^2}{p_t^2 + m_a^2}$$
 (31.9)

For K/π separation at $p=p_t=1(5)$ GeV/c, $N_{\rm p.e.}/L\approx 16(0.8)$ cm⁻¹ for π 's and (by design) 0 for K's.

For limited path lengths $N_{\rm p.e.}$ will usually be small. The overall efficiency of the device is controlled by Poisson fluctuations, which can be especially critical for separation of species where one particle type is dominant. Moreover, the effective number of photoelectrons is often less than the average number calculated above due to additional equivalent noise from the photodetector (see the discussion of the excess noise factor in Sec. 31.2 of this Review). It is common to design for at least 10 photoelectrons for the high velocity particle in order to obtain a robust counter. As rejection of the particle that is below threshold depends on not seeing a signal, electronic and other background noise can be important. Physics sources of light production for the below threshold particle, such as decay to an above threshold particle or the production of delta rays in the radiator, often limit the separation attainable, and need to be carefully considered. Well designed, modern multi-channel counters, such as the ACC at Belle [51], can attain adequate particle separation performance over a substantial momentum range for essentially the full solid angle of the spectrometer.

Imaging counters make the most powerful use of the information available by measuring the ring-correlated angles of emission of the individual Cherenkov photons. Since low-energy photon detectors can measure only the position (and, perhaps, a precise detection time) of the individual Cherenkov photons (not the angles directly), the photons must be "imaged" onto a detector so that their angles can be derived [56]. Typically the optics map the Cherenkov cone onto (a portion of) a distorted "circle" at the photodetector. Though the imaging process is directly analogous to familiar imaging techniques used in telescopes and other optical instruments, there is a somewhat bewildering variety of methods used in a wide variety of counter types with different names. Some of the imaging methods used include (1) focusing by a lens; (2) proximity focusing (i.e., focusing by limiting the emission region of the radiation); and (3) focusing through an aperture (a pinhole). In addition, the prompt Cherenkov emission coupled with the speed of modern photon detectors allows the use of (4) time imaging, a method which is little used in conventional imaging technology. Finally, (5) correlated tracking (and event reconstruction) can be performed in large water counters by combining the individual space position and time of each photon together with the constraint that Cherenkov photons are emitted from each track at the same polar angle (Sec. 32.3.1 of this Review).

In a simple model of an imaging PID counter, the fractional error on the particle velocity (δ_{β}) is given by

$$\delta_{\beta} = \frac{\sigma_{\beta}}{\beta} = \tan \theta_c \sigma(\theta_c) \quad , \tag{31.10}$$

where

$$\sigma(\theta_c) = \frac{\langle \sigma(\theta_i) \rangle}{\sqrt{N_{\text{p.e.}}}} \oplus C , \qquad (31.11)$$

and $\langle \sigma(\theta_i) \rangle$ is the average single photoelectron resolution, as defined by the optics, detector resolution and the intrinsic chromaticity spread of the radiator index of refraction averaged over the photon detection bandwidth. C combines a number of other contributions to resolution including, (1) correlated terms such as tracking, alignment, and multiple scattering, (2) hit ambiguities, (3) background hits from random sources, and (4) hits coming from other tracks. The actual separation performance is also limited by physics effects such as decays in flight and particle interactions in the material of the detector. In many practical cases, the performance is limited by these effects.

For a $\beta \approx 1$ particle of momentum (p) well above threshold entering a radiator with index of refraction (n), the number of σ separation (N_{σ}) between particles of mass m_1 and m_2 is approximately

$$N_{\sigma} \approx \frac{|m_1^2 - m_2^2|}{2p^2\sigma(\theta_c)\sqrt{n^2 - 1}}$$
 (31.12)

In practical counters, the angular resolution term $\sigma(\theta_c)$ varies between about 0.1 and 5 mrad depending on the size, radiator, and photodetector type of the particular counter. The range of momenta over which a particular counter can separate particle species extends from the point at which the number of photons emitted becomes sufficient for the counter to operate efficiently as a threshold device ($\sim 20\%$ above the threshold for the lighter species) to the value in the imaging region given by the equation above. For example, for $\sigma(\theta_c) = 2 \text{mrad}$, a fused silica radiator(n = 1.474), or a fluorocarbon gas radiator (C_5F_{12} , n = 1.0017), would separate π/K 's from the threshold region starting around 0.15(3) GeV/c through the imaging region up to about 4.2(18) GeV/c at better than 3σ .

Many different imaging counters have been built during the last several decades [57]. Among the earliest examples of this class of counters are the very limited acceptance Differential Cherenkov detectors, designed for particle selection in high momentum beam lines. These devices use optical focusing and/or geometrical masking to select particles having velocities in a specified region. With careful design, a velocity resolution of $\sigma_{\beta}/\beta \approx 10^{-4}$ – 10^{-5} can be obtained [54].

Practical multi-track <u>Ring-Imaging Cherenkov detectors</u> (generically called RICH counters) are a more recent development. RICH counters are sometimes further classified by 'generations' that differ based on historical timing, performance, design, and photodetection techniques.

Prototypical examples of first generation RICH counters are those used in the DELPHI and SLD detectors at the LEP and SLC Z factory e^+e^- colliders [57]. They have both liquid (C₆F₁₄, n=1.276) and gas $(C_5F_{12}, n = 1.0017)$ radiators, the former being proximity imaged with the latter using mirrors. The phototransducers are a TPC/wire-chamber combination. They are made sensitive to photons by doping the TPC gas (usually, ethane/methane) with $\sim 0.05\%$ TMAE (tetrakis(dimethylamino)ethylene). Great attention to detail is required, (1) to avoid absorbing the UV photons to which TMAE is sensitive, (2) to avoid absorbing the single photoelectrons as they drift in the long TPC, and (3) to keep the chemically active TMAE vapor from interacting with materials in the system. In spite of their unforgiving operational characteristics, these counters attained good $e/\pi/K/p$ separation over wide momentum ranges (from about 0.25 to 20 GeV/c) during several years of operation at LEP and SLC. Related but smaller acceptance devices include the OMEGA RICH at the CERN SPS, and the RICH in the balloon-borne CAPRICE detector [57].

Later generation counters [57] generally operate at much higher rates, with more detection channels, than the first generation detectors just described. They also utilize faster, more forgiving photon detectors, covering different photon detection bandwidths. Radiator choices have broadened to include materials such as lithium fluoride, fused silica, and aerogel. Vacuum based photodetection systems (e.g., single or multi anode PMTs, MCP PMTs, or hybrid photodiodes (HPD)) have become increasingly common (see Sec. 31.2 of this Review). They handle high rates, and can be used with a wide choice of radiators. Examples include (1) the SELEX RICH at Fermilab, which mirror focuses the Cherenkov photons from a neon radiator onto a camera array made of ~ 2000 PMTs to separate hadrons over a wide momentum range (to well above 200 GeV/c for heavy hadrons); (2) the HERMES RICH at HERA, which mirror focuses photons from $C_4F_{10}(n=1.00137)$ and aerogel(n=1.0304) radiators within the same volume onto a PMT camera array to separate hadrons in the momentum range from 2 to 15 GeV/c; and (3) the LHCb detector now being brought into operation at the LHC. It uses two separate counters. One volume, like HERMES, contains two radiators (aerogel and C_4F_{10}) while the second volume contains CF_4 . Photons are mirror focused onto detector arrays of HPDs to cover a π/K separation momentum range between 1 and 150 $\,\mathrm{GeV}/c$.

Other fast detection systems that use solid cesium iodide (CsI) photocathodes or triethylamine (TEA) doping in proportional chambers are useful with certain radiator types and geometries. Examples include (1) the CLEO-III RICH at CESR that uses a LiF radiator with TEA doped proportional chambers; (2) the ALICE detector at the LHC that uses proximity focused liquid (C_6F_{14} radiators and solid CSI photocathodes (similar photodectors have been used for several years by the HADES and COMPASS detectors), and the hadron blind detector (HBD) in the PHENIX detector at RHIC that couples a low index CF_4 radiator to a photodetector based on electron multiplier (GEM) chambers with reflective CSI photocathodes [57].

A DIRC (Detection [of] Internally Reflected Cherenkov [light]) is a distinctive, compact RICH subtype first used in the BaBar detector [52]. A DIRC "inverts" the usual RICH principle for use of light from the radiator by collecting and imaging the total internally reflected light rather than the transmitted light. It utilizes the optical material of the radiator in two ways, simultaneously; first as a Cherenkov radiator, and second, as a light pipe. The magnitudes of the photon angles are preserved during transport by the flat, rectangular cross section radiators, allowing the photons to be efficiently transported to a detector outside the path of the particle where they may be imaged in up to three independent dimensions (the usual two in space and, due to the long photon paths lengths, one in time). Because the index of refraction in the radiator is large (~ 1.48 for fused silica), the momentum range with good π/K separation is rather low. The BaBar DIRC range extends up to $\sim 4~{\rm GeV}/c$. It is plausible, but difficult, to extend it up to about 10 $\,\mathrm{GeV}/c$ with an improved design. New DIRC detectors are being developed that take advantage of the new, very fast, pixelated photodetectors becoming available, such as flat panel PMTs and MCP PMTs. They

typically utilize either time imaging or mirror focused optics, or both, leading not only to a precision measurement of the Cherenkov angle, but in some cases, to a precise measurement of the particle time of flight, and/or to correction of the chromatic dispersion in the radiator. Examples include (1) the time of propagation (TOP) counter being developed for the BELLE-II upgrade at KEKB which emphasizes precision timing for both Cherenkov imaging and TOF; (2) the full 3-dimensional imaging FDIRC for the SuperB detector at the Italian SuperB collider which uses precision timing not only for improving the angle reconstruction and TOF, but also to correct the chromatic dispersion; and (3) the DIRCs being developed for the PANDA detector at FAIR that use elegant focusing optics and fast timing [57].

31.6. Gaseous detectors

31.6.1. Energy loss and charge transport in gases: Revised March 2010 by F. Sauli (CERN) and M. Titov (CEA Saclay).

Gas-filled detectors localize the ionization produced by charged particles, generally after charge multiplication. The statistics of ionization processes having asymmetries in the ionization trails, affect the coordinate determination deduced from the measurement of drift time, or of the center of gravity of the collected charge. For thin gas layers, the width of the energy loss distribution can be larger than its average, requiring multiple sample or truncated mean analysis to achieve good particle identification. In the truncated mean method for calculating $\langle dE/dx \rangle$, the ionization measurements along the track length are broken into many samples and then a fixed fraction of high-side (and sometimes also low-side) values are rejected [58].

The energy loss of charged particles and photons in matter is discussed in Sec. 30. Table 31.5 provides values of relevant parameters in some commonly used gases at NTP (normal temperature, 20° C, and pressure, 1 atm) for unit-charge minimum-ionizing particles (MIPs) [59–65]. Values often differ, depending on the source, so those in the table should be taken only as approximate. For different conditions and for mixtures, and neglecting internal energy transfer processes (e.g., Penning effect), one can scale the density, N_P , and N_T with temperature and pressure assuming a perfect gas law.

Table 31.5: Properties of noble and molecular gases at normal temperature and pressure (NTP: 20° C, one atm). E_X , E_I : first excitation, ionization energy; W_I : average energy per ion pair; $dE/dx|_{\min}$, N_P , N_T : differential energy loss, primary and total number of electron-ion pairs per cm, for unit charge minimum ionizing particles.

When an ionizing particle passes through the gas it creates electron-ion pairs, but often the ejected electrons have sufficient energy to further ionize the medium. As shown in Table 31.5, the total number of electron-ion pairs (N_T) is usually a few times larger than the number of primaries (N_P) .

The probability for a released electron to have an energy E or larger follows an approximate $1/E^2$ dependence (Rutherford law), shown in Fig. 31.3 for Ar/CH₄ at NTP (dotted line, left scale). More detailed estimates taking into account the electronic structure of the medium are shown in the figure, for three values of the particle velocity factor $\beta\gamma$ [60]. The dot-dashed line provides, on the right scale, the

practical range of electrons (including scattering) of energy E. As an example, about 0.6% of released electrons have 1 keV or more energy, substantially increasing the ionization loss rate. The practical range of 1 keV electrons in argon (dot-dashed line, right scale) is 70 μ m and this can contribute to the error in the coordinate determination.

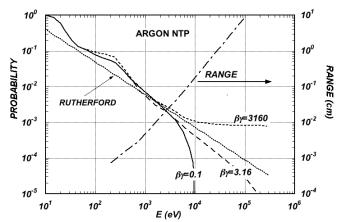

Figure 31.3: Probability of single collisions in which released electrons have an energy E or larger (left scale) and practical range of electrons in Ar/CH_4 (P10) at NTP (dot-dashed curve, right scale) [60].

The number of electron-ion pairs per primary ionization, or cluster size, has an exponentially decreasing probability; for argon, there is about 1% probability for primary clusters to contain ten or more electron-ion pairs [61].

Once released in the gas, and under the influence of an applied electric field, electrons and ions drift in opposite directions and diffuse towards the electrodes. The scattering cross section is determined by the details of atomic and molecular structure. Therefore, the drift velocity and diffusion of electrons depend very strongly on the nature of the gas, specifically on the inelastic cross-section involving the rotational and vibrational levels of molecules. In noble gases, the inelastic cross section is zero below excitation and ionization thresholds. Large drift velocities are achieved by adding polyatomic gases (usually CH₄, CO₂, or CF₄) having large inelastic cross sections at moderate energies, which results in "cooling" electrons into the energy range of the Ramsauer-Townsend minimum (at ~ 0.5 eV) of the elastic cross-section of argon. The reduction in both the total electron scattering cross-section and the electron energy results in a large increase of electron drift velocity (for a compilation of electron-molecule cross sections see Ref. 62). Another principal role of the polyatomic gas is to absorb the ultraviolet photons emitted by the excited noble gas atoms. Extensive collections of experimental data [63] and theoretical calculations based on transport theory [64] permit estimates of drift and diffusion properties in pure gases and their mixtures. In a simple approximation, gas kinetic theory provides the drift velocity v as a function of the mean collision time τ and the electric field E: $v = eE\tau/m_e$ (Townsend's expression). Values of drift velocity and diffusion for some commonly used gases at NTP are given in Fig. 31.4 and Fig. 31.5. These have been computed with the MAGBOLTZ program [65]. For different conditions, the horizontal axis must be scaled inversely with the gas density. Standard deviations for longitudinal (σ_L) and transverse diffusion (σ_T) are given for one cm of drift, and scale with the square root of the drift distance. Since the collection time is inversely proportional to the drift velocity, diffusion is less in gases such as CF₄ that have high drift velocities. In the presence of an external magnetic field, the Lorentz force acting on electrons between collisions deflects the drifting electrons and modifies the drift properties. The electron trajectories, velocities and diffusion parameters can be computed with MAGBOLTZ. A simple theory, the friction force model, provides an expression for the vector drift velocity v as a function of electric and magnetic field vectors E and B, of the

Larmor frequency $\omega = eB/m_e$, and of the mean collision time τ :

$$\boldsymbol{v} = \frac{e}{m_e} \frac{\tau}{1 + \omega^2 \tau^2} \left(\boldsymbol{E} + \frac{\omega \tau}{B} (\boldsymbol{E} \times \boldsymbol{B}) + \frac{\omega^2 \tau^2}{B^2} (\boldsymbol{E} \cdot \boldsymbol{B}) \boldsymbol{B} \right) \quad (31.13)$$

To a good approximation, and for moderate fields, one can assume that the energy of the electrons is not affected by B, and use for τ the values deduced from the drift velocity at B=0 (the Townsend expression). For \boldsymbol{E} perpendicular to \boldsymbol{B} , the drift angle to the relative to the electric field vector is $\tan\theta_B=\omega\tau$ and $v=(E/B)(\omega\tau/\sqrt{1+\omega^2\tau^2})$. For parallel electric and magnetic fields, drift velocity and longitudinal diffusion are not affected, while the transverse diffusion can be strongly reduced: $\sigma_T(B)=\sigma_T(B=0)/\sqrt{1+\omega^2\tau^2}$. The dotted line in Fig. 31.5 represents σ_T for the classic Ar/CH₄ (90:10) mixture at 4 T. Large values of $\omega\tau\sim 20$ at 5 T are consistent with the measurement of diffusion coefficient in Ar/CF₄/iC₄H₁₀ (95:3:2). This reduction is exploited in time projection chambers (Sec. 31.6.5) to improve spatial resolution.

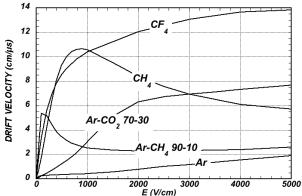

Figure 31.4: Computed electron drift velocity as a function of electric field in several gases at NTP and B = 0 [65].

In mixtures containing electronegative molecules, such as O_2 or $\mathrm{H}_2\mathrm{O}$, electrons can be captured to form negative ions. Capture cross-sections are strongly energy-dependent, and therefore the capture probability is a function of applied field. For example, the electron is attached to the oxygen molecule at energies below 1 eV. The three-body electron attachment coefficients may differ greatly for the same additive in different mixtures. As an example, at moderate fields (up to 1 kV/cm) the addition of 0.1% of oxygen to an Ar/CO₂ mixture results in an electron capture probability about twenty times larger than the same addition to Ar/CH₄.

Carbon tetrafluoride is not electronegative at low and moderate fields, making its use attractive as drift gas due to its very low diffusion. However, CF₄ has a large electron capture cross section at fields above ~ 8 kV/cm, before reaching avalanche field strengths. Depending on detector geometry, some signal reduction and resolution loss can be expected using this gas.

If the electric field is increased sufficiently, electrons gain enough energy between collisions to ionize molecules. Above a gas-dependent threshold, the mean free path for ionization, λ_i , decreases exponentially with the field; its inverse, $\alpha = 1/\lambda_i$, is the first Townsend coefficient. In wire chambers, most of the increase of avalanche particle density occurs very close to the anode wires, and a simple electrostatic consideration shows that the largest fraction of the detected signal is due to the motion of positive ions receding from the wires. The electron component, although very fast, contributes very little to the signal. This determines the characteristic shape of the detected signals in the proportional mode: a fast rise followed by a gradual increase. The slow component, the so-called "ion tail" that limits the time resolution of the detector, is usually removed by differentiation of the signal. In uniform fields, N_0 initial electrons multiply over a length xforming an electron avalanche of size $N = N_0 e^{\alpha x}$; N/N_0 is the gain of the detector. Fig. 31.6 shows examples of Townsend coefficients for several gas mixtures, computed with MAGBOLTZ [65].

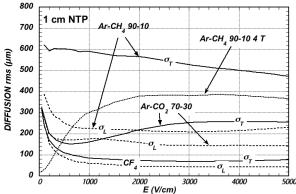

Figure 31.5: Electron longitudinal diffusion (σ_L) (dashed lines) and transverse diffusion (σ_T) (full lines) for 1 cm of drift at NTP and B=0. The dotted line shows σ_T for the P10 mixture at 4 T [65].

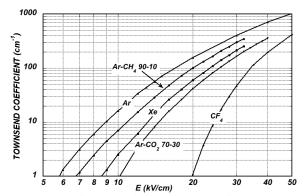

Figure 31.6: Computed first Townsend coefficient α as a function of electric field in several gases at NTP [65].

Positive ions released by the primary ionization or produced in the avalanches drift and diffuse under the influence of the electric field. Negative ions may also be produced by electron attachment to gas molecules. The drift velocity of ions in the fields encountered in gaseous detectors (up to few kV/cm) is typically about three orders of magnitude less than for electrons. The ion mobility μ , the ratio of drift velocity to electric field, is constant for a given ion type up to very high fields. Values of mobility at NTP for ions in their own and other gases are given in Table 31.6 [66]. For different temperatures and pressures, the mobility can be scaled inversely with the density assuming an ideal gas law. For mixtures, due to a very effective charge transfer mechanism, only ions with the lowest ionization potential survive after a short path in the gas. Both the lateral and transverse diffusion of ions are proportional to the square root of the drift time, with a coefficient that depends on temperature but not on the ion mass. Accumulation of ions in the gas drift volume may induce field distortions (see Sec. 31.6.5).

Table 31.6: Mobility of ions in gases at NTP [66].

| Gas | Ion | $\begin{array}{c} \text{Mobility } \mu \\ (\text{cm}^2 \ \text{V}^{-1} \ \text{s}^{-1}) \end{array}$ |

31.6.2. *Multi-Wire Proportional and Drift Chambers*: Revised March 2010 by Fabio Sauli (CERN) and Maxim Titov (CEA Saclay).

Single-wire counters that detect the ionization produced in a gas by a charged particle, followed by charge multiplication and collection around a thin wire have been used for decades. Good energy resolution is obtained in the proportional amplification mode, while very large saturated pulses can be detected in the streamer and Geiger modes [3].

Multiwire proportional chambers (MWPCs) [67,68], introduced in the late '60's, detect, localize and measure energy deposit by charged particles over large areas. A mesh of parallel anode wires at a suitable potential, inserted between two cathodes, acts almost as a set of independent proportional counters (see Fig. 31.7a). Electrons released in the gas volume drift towards the anodes and produce avalanches in the increasing field. Analytic expressions for the electric field can be found in many textbooks. The fields close to the wires E(r), in the drift region E_D , and the capacitance C per unit length of anode wire are approximately given by

$$E(r) = \frac{CV_0}{2\pi\epsilon_0} \frac{1}{r}$$
 $E_D = \frac{CV_0}{2\epsilon_0 s}$ $C = \frac{2\pi\epsilon_0}{\pi(\ell/s) - \ln(2\pi a/s)}$, (31.14)

where r is the distance from the center of the anode, s the wire spacing, ℓ and V_0 the distance and potential difference between anode and cathode, and a the anode wire radius.

Because of electrostatic forces, a node wires are in equilibrium only for a perfect geometry. Small deviations result in forces displacing the wires alternatively below and above the symmetry plane, sometimes with catastrophic results. These displacement forces are countered by the mechanical tension of the wire, up to a maximum unsupported stable length, L_M [58], above which the wire deforms:

$$L_M = \frac{s}{CV_0} \sqrt{4\pi\epsilon_0 T_M} \tag{31.15}$$

The maximum tension T_M depends on the wire diameter and modulus of elasticity. Table 31.7 gives approximate values for tungsten and the corresponding maximum stable wire length under reasonable assumptions for the operating voltage ($V_0 = 5 \,\mathrm{kV}$) [69]. Internal supports and spacers can be used in the construction of longer detectors to overcome limits on the wire length imposed by Eq. (31.15).

Table 31.7: Maximum tension T_M and stable unsupported length L_M for tungsten wires with spacing s, operated at $V_0 = 5$ kV. No safety factor is included.

| Wire diameter (μm) | T_M (newton) | s (mm) | L_M (cm) |
|--------------------|----------------|--------|------------|
| 10 | 0.16 | 1 | 25 |
| 20 | 0.65 | 2 | 85 |

Detection of charge on the wires over a predefined threshold provides the transverse coordinate to the wire with an accuracy comparable to that of the wire spacing. The coordinate along each wire can be obtained by measuring the ratio of collected charge at the two ends of resistive wires. Making use of the charge profile induced on segmented cathodes, the so-called center-of gravity (COG) method, permits localization of tracks to sub-mm accuracy. Due to the statistics of energy loss and asymmetric ionization clusters, the position accuracy is $\sim 50\,\mu\mathrm{m}$ rms for tracks perpendicular to the wire plane, but degrades to $\sim 250\,\mu\mathrm{mat}$ 30° to the normal [70]. The intrinsic bi-dimensional characteristic of the COG readout has found numerous applications in medical imaging.

Drift chambers, developed in the early '70's, can be used to estimate the longitudinal position of a track by exploiting the arrival time of electrons at the anodes if the time of interaction is known [71]. The distance between anode wires is usually several cm, allowing coverage of large areas at reduced cost. In the original design, a thicker wire (the field wire) at the proper voltage, placed between the anode wires, reduces the field at the mid-point between anodes and improves

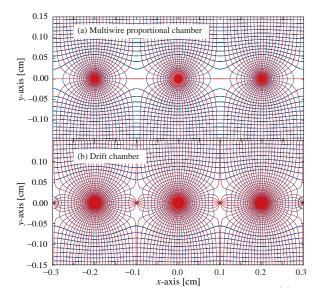

Figure 31.7: Electric field lines and equipotentials in (a) a multiwire proportional chamber and (b) a drift chamber.

charge collection (Fig. 31.7b). In some drift chamber designs, and with the help of suitable voltages applied to field-shaping electrodes, the electric field structure is adjusted to improve the linearity of space-to-drift-time relation, resulting in better spatial resolution [72].

Drift chambers can reach a longitudinal spatial resolution from timing measurement of order 100 µm (rms) or better for minimum ionizing particles, depending on the geometry and operating conditions. However, a degradation of resolution is observed [73] due to primary ionization statistics for tracks close to the anode wires, caused by the spread in arrival time of the nearest ionization clusters. The effect can be reduced by operating the detector at higher pressures. Sampling the drift time on rows of anodes led to the concept of multiple arrays such as the multi-drift module [74] and the JET chamber [75]. A measurement of drift time, together with the recording of charge sharing from the two ends of the anode wires provides the coordinates of segments of tracks. The total charge gives information on the differential energy loss and is exploited for particle identification. The time projection chamber (TPC) [76] combines a measurement of drift time and charge induction on cathodes, to obtain excellent tracking for high multiplicity topologies occurring at moderate rates (see Sec. 31.6.5). In all cases, a good knowledge of electron drift velocity and diffusion properties is required. This has to be combined with the knowledge of the electric fields in the structures, computed with commercial or custom-developed software [65,77]. For an overview of detectors exploiting the drift time for coordinate measurement see Refs. 6 and 58.

Multiwire and drift chambers have been operated with a variety of gas fillings and operating modes, depending on experimental requirements. The so-called "Magic Gas," a mixture of argon, isobutane and Freon [68], permits very high and saturated gains ($\sim 10^6$). This gas mixture was used in early wire chambers, but was found to be susceptible to severe aging processes. With present-day electronics, proportional gains around 10^4 are sufficient for detection of minimum ionizing particles, and noble gases with moderate amounts of polyatomic gases, such as methane or carbon dioxide, are used.

Although very powerful in terms of performance, multi-wire structures have reliability problems when used in harsh or hard-to-access environments, since a single broken wire can disable the entire detector. Introduced in the '80's, straw and drift tube systems make use of large arrays of wire counters encased in individual enclosures, each acting as an independent wire counter [78]. Techniques for low-cost mass production of these detectors have been developed for large experiments, such as the Transition Radiation Tracker and the Drift Tubes arrays for CERN's LHC experiments [79].

31.6.3. *High Rate Effects*: Revised March 2010 by Fabio Sauli (CERN) and Maxim Titov (CEA Saclay).

The production of positive ions in the avalanches and their slow drift before neutralization result in a rate-dependent accumulation of positive charge in the detector. This may result in significant field distortion, gain reduction and degradation of spatial resolution. As shown in Fig. 31.8 [80], the proportional gain drops above a charge production rate around 10^9 electrons per second and mm of wire, independently of the avalanche size. For a proportional gain of 10^4 and 100 electrons per track, this corresponds to a particle flux of $10^3 \, \mathrm{s^{-1}mm^{-1}}$ (1 kHz/mm² for 1 mm wire spacing).

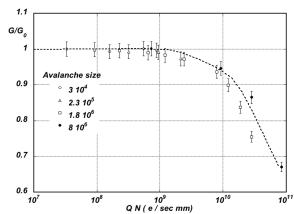

Figure 31.8: Charge rate dependence of normalized gas gain G/G_0 (relative to zero counting rate) in proportional thin-wire detectors [80]. Q is the total charge in single avalanche; N is the particle rate per wire length.

At high radiation fluxes, a fast degradation of detectors due to the formation of polymers deposits (aging) is often observed. The process has been extensively investigated, often with conflicting results. Several causes have been identified, including organic pollutants and silicone oils. Addition of small amounts of water in many (but not all) cases has been shown to extend the lifetime of the detectors. Addition of fluorinated gases (e.g., CF₄) or oxygen may result in an etching action that can overcome polymer formation, or even eliminate already existing deposits. However, the issue of long-term survival of gas detectors with these gases is controversial [81]. Under optimum operating conditions, a total collected charge of a few coulombs per cm of wire can usually be reached before noticeable degradation occurs. This corresponds, for one mm spacing and at a gain of 10^4 , to a total particle flux of $\sim 10^{14}$ MIPs/cm².

31.6.4. *Micro-Pattern Gas Detectors*: Revised March 2010 by Fabio Sauli (CERN) and Maxim Titov (CEA Saclay)

Despite various improvements, position-sensitive detectors based on wire structures are limited by basic diffusion processes and space charge effects to localization accuracies of $50\text{--}100\,\mu\mathrm{m}$ [82]. Modern photolithographic technology led to the development of novel Micro-Pattern Gas Detector (MPGD) concepts [83], revolutionizing cell size limitations for many gas detector applications. By using pitch size of a few hundred $\mu\mathrm{m}$, an order of magnitude improvement in granularity over wire chambers, these detectors offer intrinsic high rate capability (> 10^6 Hz/mm²), excellent spatial resolution ($\sim 30~\mu\mathrm{m}$), multi-particle resolution ($\sim 500~\mu\mathrm{m}$), and single photo-electron time resolution in the ns range.

The Micro-Strip Gas Chamber (MSGC), invented in 1988, was the first of the micro-structure gas chambers [84]. It consists of a set of tiny parallel metal strips laid on a thin resistive support, alternatively connected as anodes and cathodes. Owing to the small anode-to-cathode distance ($\sim 100~\mu m$), the fast collection of positive ions reduces space charge build-up, and provides a greatly increased rate capability. Unfortunately, the fragile electrode structure of the MSGC turned out to be easily destroyed by discharges induced by heavily ionizing particles [85]. Nevertheless, detailed studies of their properties, and in particular, on the radiation-induced processes

leading to discharge breakdown, led to the development of the more powerful devices: GEM and Micromegas. These have improved reliability and radiation hardness. The absence of space-charge effects in GEM detectors at the highest rates reached so far and the fine granularity of MPGDs improve the maximum rate capability by more than two orders of magnitude (Fig. 31.9) [72,86]. Even larger rate capability has been reported for Micromegas [87].

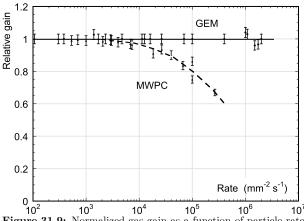

Figure 31.9: Normalized gas gain as a function of particle rate for MWPC [72] and GEM [86].

The Gas Electron Multiplier (GEM) detector consists of a thin-foil copper-insulator-copper sandwich chemically perforated to obtain a high density of holes in which avalanches occur [88]. The hole diameter is typically between 25 μ m and 150 μ m, while the corresponding distance between holes varies between 50 μ m and 200 μ m. The central insulator is usually (in the original design) the polymer Kapton, with a thickness of 50 μ m. Application of a potential difference between the two sides of the GEM generates the electric fields indicated in Fig. 31.10. Each hole acts as an independent proportional counter. Electrons released by the primary ionization particle in the upper conversion region (above the GEM foil) drift into the holes, where charge multiplication occurs in the high electric field (50-70 kV/cm). Most of avalanche electrons are transferred into the gap below the GEM. Several GEM foils can be cascaded, allowing the multi-layer GEM detectors to operate at overall gas gain above 10⁴ in the presence of highly ionizing particles, while strongly reducing the risk of discharges. This is a major advantage of the GEM technology [89]. Localization can then be performed by collecting the charge on a patterned one- or two-dimensional readout board of arbitrary pattern, placed below the last GEM.

The micro-mesh gaseous structure (Micromegas) is a thin parallelplate avalanche counter, as shown in Fig. 31.11 [90]. It consists of a drift region and a narrow multiplication gap (25–150 μ m) between a thin metal grid (micromesh) and the readout electrode (strips or pads of conductor printed on an insulator board). Electrons from the primary ionization drift through the holes of the mesh into the narrow multiplication gap, where they are amplified. The electric field is homogeneous both in the drift (electric field ~1 kV/cm) and amplification (50-70 kV/cm) gaps. In the narrow multiplication region, gain variations due to small variations of the amplification gap are approximately compensated by an inverse variation of the amplification coefficient, resulting in a more uniform gain. The small amplification gap produces a narrow avalanche, giving rise to excellent spatial resolution: 12 μ m accuracy, limited by the micro-mesh pitch, has been achieved for MIPs, as well as very good time resolution and energy resolution ($\sim 12\%$ FWHM with 6 keV x rays) [91].

The performance and robustness of GEM and Micromegas have encouraged their use in high-energy and nuclear physics, UV and visible photon detection, astroparticle and neutrino physics, neutron detection and medical physics. Most structures were originally optimized for high-rate particle tracking in nuclear and high-energy physics experiments. COMPASS, a high-luminosity experiment at CERN, pioneered the use of large-area ($\sim 40 \times 40~\text{cm}^2$) GEM and

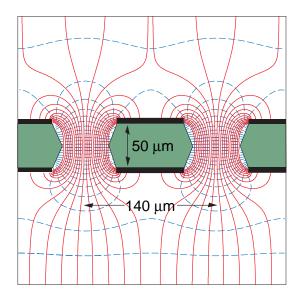

Figure 31.10: Schematic view and typical dimensions of the hole structure in the GEM amplification cell. Electric field lines (solid) and equipotentials (dashed) are shown.

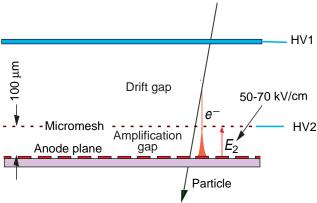

Figure 31.11: Schematic drawing of the Micromegas detector.

Micromegas detectors close to the beam line with particle rates of $25~\mathrm{kHz/mm^2}$. Both technologies achieved a tracking efficiency of close to 100% at gas gains of about 10^4 , a spatial resolution of $70{\text -}100~\mu\mathrm{m}$ and a time resolution of $\sim 10~\mathrm{ns}$. GEM detectors are also used for triggering in the LHCb Muon System and for tracking in the TOTEM Telescopes. Both GEM and Micromegas devices are foreseen for the upgrade of the LHC experiments and for one of the readout options for the Time Projection Chamber (TPC) at the International Linear Collider (ILC). The development of new fabrication techniques—"bulk" Micromegas technology [92] and single-mask GEMs [93] —is a big step toward industrial production of large-size MPGDs. In some applications requiring very large-area coverage with moderate spatial resolution, coarse macro-patterned detectors, such as Thick GEMs (THGEM) [94] or patterned resistive-plate devices [95] might offer economically interesting solutions.

Sensitive and low-noise electronics enlarge the range of the MPGD applications. Recently, the GEM and Micromegas detectors were read out by high-granularity ($\sim 50~\mu\mathrm{m}$ pitch) CMOS chips assembled directly below the GEM or Micromegas amplification structures [96]. These detectors use the bump-bonding pads of a pixel chip as an integrated charge collecting anode. With this arrangement signals are induced at the input gate of a charge-sensitive preamplifier (top metal layer of the CMOS chip). Every pixel is then directly connected to the amplification and digitization circuits, integrated in the underlying active layers of the CMOS technology, yielding timing and charge measurements as well as precise spatial information in 3D.

The operation of a MPGD with a Timepix CMOS chip has

demonstrated the possibility of reconstructing 3D-space points of individual primary electron clusters with $\sim\!30\,\mu\mathrm{m}$ spatial resolution and event-time resolution with nanosecond precision. This has become indispensable for tracking and triggering and also for discriminating between ionizing tracks and photon conversions. The GEM, in conjunction with a CMOS ASIC,* can directly view the absorption process of a few keV x-ray quanta and simultaneously reconstruct the direction of emission, which is sensitive to the x-ray polarization. Thanks to these developments, a micro-pattern device with finely segmented CMOS readout can serve as a high-precision "electronic bubble chamber." This may open new opportunities for x-ray polarimeters, detection of weakly interacting massive particles (WIMPs) and axions, Compton telescopes, and 3D imaging of nuclear recoils.

An elegant solution for the construction of the Micromegas with pixel readout is the integration of the amplification grid and CMOS chip by means of an advanced "wafer post-processing" technology [97]. This novel concept is called "Ingrid" (see Fig. 31.12). With this technique, the structure of a thin $(1\,\mu\mathrm{m})$ aluminum grid is fabricated on top of an array of insulating pillars. which stands $\sim 50\,\mu\mathrm{m}$ above the CMOS chip. The sub- $\mu\mathrm{m}$ precision of the grid dimensions and avalanche gap size results in a uniform gas gain. The grid hole size, pitch and pattern can be easily adapted to match the geometry of any pixel readout chip.

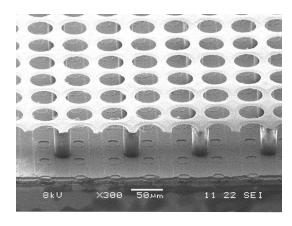

Figure 31.12: Photo of the Micromegas "Ingrid" detector. The grid holes can be accurately aligned with readout pixels of CMOS chip. The insulating pillars are centered between the grid holes, thus avoiding dead regions.

Recent developments in radiation hardness research with state-of-the-art MPGDs are reviewed in Ref. 98. Earlier aging studies of GEM and Micromegas concepts revealed that they might be even less vulnerable to radiation-induced performance degradation than standard silicon microstrip detectors.

The RD51 collaboration was established in 2008 to further advance technological developments of micro-pattern detectors and associated electronic-readout systems for applications in basic and applied research [99].

^{*} Application Specific Integrated Circuit

31.6.5. *Time-projection chambers*: Reviser October 2011 by D. Karlen (U. of Victoria and TRIUMF, Canada)

The Time Projection Chamber (TPC) concept, invented by David Nygren in the late 1970's [76], is the basis for charged particle tracking in a large number of particle and nuclear physics experiments. A uniform electric field drifts tracks of electrons produced by charged particles traversing a medium, either gas or liquid, towards a surface segmented into 2D readout pads. The signal amplitudes and arrival times are recorded to provide full 3D measurements of the particle trajectories. The intrinsic 3D segmentation gives the TPC a distinct advantage over other large volume tracking detector designs which record information only in a 2D projection with less overall segmentation, particularly for pattern recognition in events with large numbers of particles.

Gaseous TPC's are often designed to operate within a strong magnetic field (typically parallel to the drift field) so that particle momenta can be estimated from the track curvature. For this application, precise spatial measurements in the plane transverse to the magnetic field are most important. Since the amount of ionization along the length of the track depends on the velocity of the particle, ionization and momentum measurements can be combined to identify the types of particles observed in the TPC. The estimator for the energy deposit by a particle is usually formed as the truncated mean of the energy deposits, using the 50%–70% of the samples with the smallest signals. Variance due to energetic δ -ray production is thus reduced.

Gas amplification of 10^3-10^4 at the readout endplate is usually required in order to provide signals with sufficient amplitude for conventional electronics to sense the drifted ionization. Until recently, the gas amplification system used in TPC's have exclusively been planes of anode wires operated in proportional mode placed close to the readout pads. Performance has been recently improved by replacing these wire planes with micro-pattern gas detectors, namely GEM [88] and Micromegas [90] devices. Advances in electronics miniaturization have been important in this development, allowing pad areas to be reduced to the 10 mm² scale or less, well matched to the narrow extent of signals produced with micro-pattern gas detectors. Presently, the ultimate in fine segmentation TPC readout are silicon sensors, with 0.05 mm \times 0.05 mm pixels, in combination with GEM or Micromegas [100]. With such fine granularity it is possible to count the number of ionization clusters along the length of a track which, in principle, can improve the particle identification capability.

Examples of two modern large volume gaseous TPC's are shown in Fig. 31.13 and Fig. 31.14. The particle identification performance is illustrated in Fig. 31.15, for the original TPC in the PEP-4/9 experiment [101].

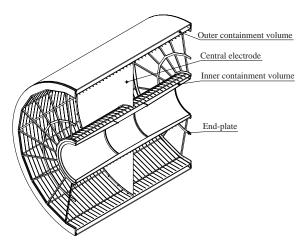

Figure 31.13: The ALICE TPC shown in a cutaway view [102]. The drift volume is 5 m long with a 5 m diameter. Gas amplification is provided by planes of anode wires.

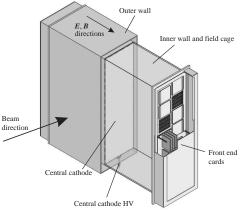

Figure 31.14: One of the 3 TPC modules for the near detector of the T2K experiment [103]. The drift volume is $2 \text{ m} \times 2 \text{ m} \times 0.8 \text{ m}$. Micromegas devices are used for gas amplification and readout.

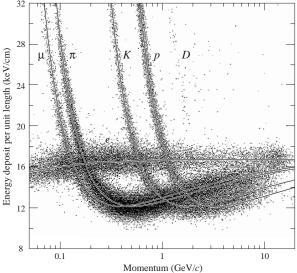

Figure 31.15: The PEP4/9-TPC energy deposit measurements (185 samples, 8.5 atm Ar-CH₄ 80:20). The ionization rate at the Fermi plateau (at high β) is 1.4 times that for the minimum at lower β . This ratio increases to 1.6 at atmospheric pressure.

The greatest challenges for a large TPC arise from the long drift distance, typically 100 times further than in a comparable wire chamber design. In particular, the long drift distance can make the device sensitive to small distortions in the electric field. Distortions can arise from a number of sources, such as imperfections in the TPC construction, deformations of the readout surface, or the presence of ions in the active medium.

For a gaseous TPC operated in a magnetic field, the electron drift velocity \boldsymbol{v} is defined by Eq. (31.13). With a strong magnetic field parallel to the electric field and a gas with a large value of $\omega\tau$ (also favored to reduce transverse diffusion as discussed below), the transverse displacements of the drifting electrons due to electric field distortions are reduced. In this mode of operation, it is essential to precisely map the magnetic field as the electron drift lines closely follow the magnetic field lines. Corrections for electric and/or magnetic field non-uniformities can be determined from control samples of electrons produced by ionizing the gas with UV laser beams, from photoelectrons produced on the cathode, or from tracks emanating from calibration reactions.

The long drift distance means that there is a delay, typically $10-100~\mu s$ in a large gaseous TPC, for signals to arrive at the endplate. For experiments with shorter intervals between events, this

can produce ambiguities in the starting time for the drift of ionization. This can be resolved by matching the TPC data with that from an auxiliary detector providing additional spatial or timing information.

In a gaseous TPC, the motion of positive ions is much slower than the electrons, and so the positive ions produced by many events may exist in the active volume. Of greatest concern is the ions produced in the gas amplification stage. Large gaseous TPC's built until now with wire planes have included a gating grid that prevent the positive ions from escaping into the drift volume in the interval between event triggers. Micro-pattern gas detectors release much less positive ions than wire planes operating at the same gain, which may allow operation of a TPC without a gating grid.

Given the long drift distance in a large TPC, the active medium must remain very pure, as small amounts of contamination can absorb the ionization signal. For example, in a typical large gaseous TPC, O_2 must be kept below a few parts in 10^5 , otherwise a large fraction of the drifting electrons will become attached. Special attention must be made in the choice of construction materials in order to avoid the release of other electronegative contaminants.

Diffusion degrades the position information of ionization that drifts a long distance. For a gaseous TPC, the effect can be alleviated by the choice of a gas with low intrinsic diffusion or by operating in a strong magnetic field parallel to the drift field with a gas which exhibits a significant reduction in transverse diffusion with magnetic field. For typical operation without magnetic field, the transverse extent of the electrons, σ_{Dx} , is a few mm after drifting 1 m due to diffusion. With a strong magnetic field, σ_{Dx} can be reduced by as much as a factor of 10,

$$\sigma_{Dx}(B)/\sigma_{Dx}(0) = \frac{1}{\sqrt{1+\omega^2\tau^2}}$$
 (31.16)

where $\omega \tau$ is defined above. The diffusion limited position resolution from the information collected by a single row of pads is

$$\sigma_x = \frac{\sigma_{Dx}}{\sqrt{n}} \tag{31.17}$$

where n is the effective number of electrons collected by the pad row, giving an ultimate single row resolution of order 100 μ m.

Diffusion is significantly reduced in a negative-ion TPC [104], which uses a special gas mixture that attaches electrons immediately as they are produced. The drifting negative ions exhibit much less diffusion than electrons. The slow drift velocity and small $\omega \tau$ of negative ions must be compatible with the experimental environment.

The spatial resolution achieved by a TPC is determined by a number of factors in addition to diffusion. Non-uniform ionization along the length of the track is a particularly important factor, and is responsible for the so-called "track angle" and " $E \times B$ " effects. If the boundaries between pads in a row are not parallel to the track, the ionization fluctuations will increase the variance in the position estimate from that row. For this reason, experiments with a preferred track direction should have pad boundaries aligned with that direction. Traditional TPC's with wire plane amplification suffer from the effects of non-parallel electric and magnetic fields near the wires that rotate ionization segments, thereby degrading the resolution because of the non-uniform ionization. Micro-pattern gas detectors exhibit a much smaller $E \times B$ effect, since their feature size is much smaller than that of a wire grid.

31.6.6. Transition radiation detectors (TRD's): Written August 2007 by P. Nevski (BNL) and A. Romaniouk (Moscow Eng. & Phys. Inst.)

Transition radiation (TR) x rays are produced when a highly relativistic particle ($\gamma \gtrsim 10^3$) crosses a refractive index interface, as discussed in Sec. 30.7. The x rays, ranging from a few keV to a few dozen keV, are emitted at a characteristic angle $1/\gamma$ from the particle trajectory. Since the TR yield is about 1% per boundary crossing, radiation from multiple surface crossings is used in practical detectors. In the simplest concept, a detector module might consist of low-Z foils followed by a high-Z active layer made of proportional counters filled with a Xe-rich gas mixture. The atomic number considerations follow from the dominant photoelectric absorption cross section per atom going roughly as Z^n/E_x^3 , where n varies between 4 and 5 over

the region of interest, and the x-ray energy is E_x .* To minimize self-absorption, materials such as polypropylene, Mylar, carbon, and (rarely) lithium are used as radiators. The TR signal in the active regions is in most cases superimposed upon the particle's ionization losses. These drop a little faster than Z/A with increasing Z, providing another reason for active layers with high Z.

The TR intensity for a single boundary crossing always increases with γ , but for multiple boundary crossings interference leads to saturation near a Lorentz factor $\gamma_{\rm sat}=0.6~\omega_1\sqrt{\ell_1\ell_2}/c~[105]$, where ω_1 is the radiator plasma frequency, ℓ_1 is its thickness, and ℓ_2 the spacing. In most of the detectors used in particle physics the radiator parameters are chosen to provide $\gamma_{\rm sat}\approx 2000$. Those detectors normally work as threshold devices, ensuring the best electron/pion separation in the momentum range 1 GeV/ $c\lesssim p\lesssim 150~{\rm GeV}/c$.

One can distinguish two design concepts—"thick" and "thin" detectors:

- 1. The radiator, optimized for a minimum total radiation length at maximum TR yield and total TR absorption, consists of few hundred foils (for instance 300 20 μm thick polypropylene foils). A dominant fraction of the soft TR photons is absorbed in the radiator itself. To increase the average TR photon energy further, part of the radiator far from the active layers is often made of thicker foils. The detector thickness, about 2 cm for Xe-filled gas chambers, is optimized to absorb the shaped x-ray spectrum. A classical detector is composed of several similar modules which respond nearly independently. Such detectors were used in the NA34 [106], and are being used in the ALICE experiment [107].
- 2. In another TRD concept a fine granular radiator/detector structure exploits the soft part of the TR spectrum more efficiently. This can be achieved, for instance, by distributing small-diameter straw-tube detectors uniformly or in thin layers throughout the radiator material (foils or fibers). Even with a relatively thin radiator stack, radiation below 5 keV is mostly lost in the radiators themselves. However for photon energies above this value the absorption becomes smaller and the radiation can be registered by several consecutive detector layers, thus creating a strong TR build-up effect. Descriptions of detectors using this approach can be found in both accelerator and space experiments [107]. For example, in the ATLAS TR tracker charged particles cross about 35 effective straw tube layers embedded in the radiator material [107]. The effective thickness of the Xe gas per straw is about 2.3 mm and the average number of foils per straw is about 40 with an effective foil thickness of about 20 μ m.

Both TR photon absorption and the TR build-up significantly affect the detector performance. Although the values mentioned above are typical for most of the plastic radiators used with Xe-based detectors, they vary significantly depending on detector parameters: radiator material, thickness and spacing, the construction of the sensitive chambers, their position, etc. Thus careful simulations are usually needed to build a detector optimized for a particular application.

The discrimination between electrons and pions can be based on the charge deposition measured in each detection module, on the number of clusters—energy depositions observed above an optimal threshold (usually in the 5 to 7 keV region), or on more sophisticated methods analyzing the pulse shape as a function of time. The total energy measurement technique is more suitable for thick gas volumes, which absorb most of the TR radiation and where the ionization loss fluctuations are small. The cluster-counting method works better for detectors with thin gas layers, where the fluctuations of the ionization losses are big. Cluster-counting replaces the Landau-Vavilov distribution of background ionization energy losses with the Poisson statistics of δ -electrons, responsible for the distribution tails. The latter distribution is narrower that the Landau-Vavilov distribution.

The major factor in the performance of any TRD is its overall length. This is illustrated in Fig. 31.16, which shows, for a variety of detectors, the pion efficiency at a fixed electron efficiency of 90% as a function of the overall detector length. The experimental data, covering a range of particle energies from a few GeV to 40 GeV, are

^{*} Photon absorption coefficients for the elements (via a NIST link), and $dE/dx|_{\rm min}$ and plasma energies for many materials are given in pdg.lbl.gov/AtomicNuclearProperties.

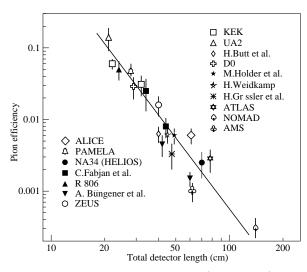

Figure 31.16: Pion efficiency measured (or predicted) for different TRDs as a function of the detector length for a fixed electron efficiency of 90%. The plot is taken from [106] with efficiencies of more recent detectors added [107].

rescaled to an energy of 10 GeV when possible. Phenomenologically, the rejection power against pions increases as $5\cdot 10^{L/38}$, where the range of validity is $L\approx 20$ –100 cm.

Many recent TRDs combine particle identification with charged-track measurement in the same detector [107]. This provides a powerful tool for electron identification even at very high particle densities. Another example of this combination is described by Brigida et al. in Ref. 107. In this work Si-microstrip detectors operating in a magnetic filed are used both for particle and TR detection. The excellent coordinate resolution of the Si detectors allows spatial separation of the TR photons from particle ionization tracks with relatively modest distances between radiator and detector.

Recent TRDs for particle astrophysics are designed to directly measure the Lorentz factor of high-energy nuclei by using the quadratic dependence of the TR yield on nuclear charge; see Cherry and Müller papers in Ref. 107. The radiator configuration (ℓ_1, ℓ_2) is tuned to extend the TR yield rise up to $\gamma \lesssim 10^5$ using more energetic part of the TR spectrum (up to 100 keV). Exotic radiator materials such as aluminum and unusual TR detection methods (Compton scattering) are used such cases.

31.6.7. Resistive-plate chambers: Revised September 2007 by H.R. Band (U. Wisconsin).

The resistive-plate chamber (RPC) was developed by Santonico and Cardarelli in the early 1980's [108] as a low-cost alternative to large scintillator planes.* Most commonly, an RPC is constructed from two parallel high-resistivity $(10^9-10^{13} \ \Omega\text{-cm})$ glass or phenolic (Bakelite)/melamine laminate plates with a few-mm gap between them which is filled with atmospheric-pressure gas. The gas is chosen to absorb UV photons in order to limit transverse growth of discharges. The backs of the plates are coated with a lower-resistivity paint or ink $(\sim 10^5 \,\Omega/\Box)$, and a high potential (7–12 kV) is maintained between them. The passage of a charged particle initiates an electric discharge, whose size and duration are limited since the current reduces the local potential to below that needed to maintain the discharge. The sensitivity of the detector outside of this region is unaffected. The signal readout is via capacitive coupling to metallic strips on both sides of the detector which are separated from the high voltage coatings by thin insulating sheets. The x and y position of the discharge can be measured if the strips on opposite sides of the gap are orthogonal. When operated in streamer mode, the induced signals on the strips can be quite large (~300 mV), making sensitive electronics unnecessary. An example of an RPC structure is shown in Fig. 31.17.

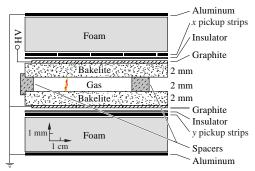

Figure 31.17: Schematic cross section of a typical RPC, in this case the single-gap streamer-mode BaBar RPC.

RPC's have inherent rate limitations since the time needed to re-establish the field after a discharge is proportional to the chamber capacitance and plate resistance. The average charge per streamer is 100-1000 pC. Typically, the efficiency of streamer-mode glass RPC's begins to fall above $\sim 0.4~{\rm Hz/cm^2}$. Because of Bakelite's lower bulk resistivity, Bakelite RPC's can be efficient at $10-100~{\rm Hz/cm^2}$. The need for higher rate capability led to the development of avalanchemode RPC's, in which the gas and high voltage have been tuned to limit the growth of the electric discharge, preventing streamer formation. Typical avalanchemode RPC's have a signal charge of about $10~{\rm pC}$ and can be efficient at $1~{\rm kHz/cm^2}$. The avalanche discharge produces a much smaller induced signal on the pickup strips ($\sim 1~{\rm mV}$) than streamers, and thus requires a more sophisticated and careful electronic design.

Many variations of the initial RPC design have been built for operation in either mode. Efficiencies of $\gtrsim 92\%$ for single gaps can be improved by the use of two or more gas gaps with shared pickup strips. Non-flammable and more environmentally friendly gas mixtures have been developed. In streamer mode, various mixtures of argon with isobutane and tetrafluoroethane have been used. For avalanche mode operation, a gas mixture of tetrafluoroethane (C₂H₂F₄) with 2–5% isobutane and 0.4–10% sulfur hexafluoride (SF₆) is typical. An example of large-scale RPC use is provided by the muon system being built for the ATLAS detector, where three layers of pairs of RPC's are used to trigger the drift tube arrays between the pairs. The total area is about 10,000 m². These RPC's provide a spatial resolution of 1 cm and a time resolution of 1 ns at an efficiency $\geq 99\%$.

Developments of multiple-gap RPC's [110] lead to RPC designs with much better timing resolution ($\sim 50\,\mathrm{ps}$) for use in time-of-flight particle identification systems. A pioneering design used by the HARP experiment [111] has two sets of 2 thin gas gaps (0.3 mm) separated by thin(0.7 mm) glass plates. The outer plates are connected to high voltage and ground while the inner plate is electrically isolated and floats to a stable equilibrium potential. The observed RPC intrinsic time resolution of 127 ps may have been limited by amplifier noise. Fonte provides useful review [112] of other RPC designs.

Operational experience with RPC's has been mixed. Several experiments (e.g., L3 and HARP) have reported reliable performance. However, the severe problems experienced with the BaBar RPC's have raised concerns about the long-term reliability of Bakelite RPC's.

Glass RPC's have had fewer problems, as seen by the history of the BELLE chambers. A rapid growth in the noise rate and leakage current in some of the BELLE glass RPC's was observed during commissioning. It was found that water vapor in the input gas was reacting with fluorine (produced by the disassociation of the tetrafluoroethane in the streamers) to produce hydrofluoric acid. The acid etched the glass surfaces, leading to increased noise rates and lower efficiencies. The use of copper gas piping to insure the dryness of the input gas stopped the problem. The BELLE RPC's have now operated reliably for more than 5 years.

Several different failure modes diagnosed in the first-generation BaBar Bakelite RPC's caused the average efficiency of the barrel RPC's to fall from $\gtrsim 90\%$ to 35% in five years. The linseed oil which is used in Bakelite RPC's to coat the inner surface [113] had not been completely cured. Under warm conditions (32° C)

^{*} It was based on earlier work on a spark counter with one high-resistivity plate [109].

and high voltage, oil collected on the spacers between the gaps or formed oil-drop bridges between the gaps. This led to large leakage currents (50–100 μ A in some chambers) which persisted even when the temperature was regulated at 20° C. In addition, the graphite layer used to distribute the high voltage over the Bakelite became highly resistive $(100 \,\mathrm{k}\Omega/\Box \to 10 \,\mathrm{M}\Omega/\Box)$, resulting in lowered efficiency in some regions and the complete death of whole chambers.

The BaBar problems and the proposed use of Bakelite RPC's in the LHC detectors prompted detailed studies of RPC aging and have led to improved construction techniques and a better understanding of RPC operational limits. The graphite layer has been improved and should be stable with integrated currents of $\lesssim 600 \,\mathrm{mC/cm^2}$. Molded gas inlets and improved cleanliness during construction have reduced the noise rate of new chambers. Unlike glass RPC's, Bakelite RPC's have been found to require humid input gases to prevent drying of the Bakelite (increasing the bulk resistivity) which would decrease the rate capability. Second-generation BaBar RPC's incorporating many of the above improvements have performed reliably for over two years [114].

With many of these problems solved, new-generation RPC's are now being or soon will be used in about a dozen cosmic-ray and HEP detectors. Their comparatively low cost, ease of construction, good time resolution, high efficiency, and moderate spatial resolution make them attractive in many situations, particularly those requiring fast timing and/or large-area coverage.

31.7. Semiconductor detectors

Updated August 2011 by H. Spieler.

Semiconductor detectors provide a unique combination of energy and position resolution. In collider detectors they are most widely used as position sensing devices and photodetectors (Sec. 31.2). Integrated circuit technology allows the formation of high-density micron-scale electrodes on large (15–20 cm diameter) wafers, providing excellent position resolution. Furthermore, the density of silicon and its small ionization energy yield adequate signals with active layers only 100–300 μ m thick, so the signals are also fast (typically tens of ns). The high energy resolution is a key parameter in x-ray, gamma, and charged particle spectroscopy, e.g., in neutrinoless double beta decay searches. Silicon and germanium are the most commonly used materials, but gallium-arsenide, CdTe, CdZnTe, and other materials are also useful. CdZnTe provides a higher stopping power and the ratio of Cd to Zn concentrations changes the bandgap. Ge detectors are commonly operated at liquid nitrogen temperature to reduce the bias current, which depends exponentially on temperature. Semiconductor detectors depend crucially on low-noise electronics (see Sec. 31.8), so the detection sensitivity is determined by signal charge and capacitance. For a comprehensive discussion of semiconductor detectors and electronics see Ref. 115.

31.7.1. Materials Requirements:

Semiconductor detectors are essentially solid state ionization chambers. Absorbed energy forms electron-hole pairs, i.e., negative and positive charge carriers, which under an applied electric field move towards their respective collection electrodes, where they induce a signal current. The energy required to form an electron-hole pair is proportional to the bandgap. In tracking detectors the energy loss in the detector should be minimal, whereas for energy spectroscopy the stopping power should be maximized, so for gamma rays high-Zmaterials are desirable.

Measurements on silicon photodiodes [116] show that for photon energies below 4 eV one electron-hole (e-h) pair is formed per incident photon. The mean energy E_i required to produce an e-h pair peaks at 4.4 eV for a photon energy around 6 eV. Above $\sim 1.5 \text{ keV}$ it assumes a constant value, 3.67 eV at room temperature. It is larger than the bandgap energy because momentum conservation requires excitation of lattice vibrations (phonons). For minimum-ionizing particles, the most probable charge deposition in a 300 μ m thick silicon detector is about 3.5 fC (22000 electrons). Other typical ionization energies are 2.96 eV in Ge, 4.2 eV in GaAs, and 4.43 eV in CdTe.

Since both electronic and lattice excitations are involved, the variance in the number of charge carriers $N = E/E_i$ produced by an absorbed energy E is reduced by the Fano factor F (about 0.1 in Si and Ge). Thus, $\sigma_N = \sqrt{FN}$ and the energy resolution

 $\sigma_E/E = \sqrt{FE_i/E}$. However, the measured signal fluctuations are usually dominated by electronic noise or energy loss fluctuations in the detector. The electronic noise contributions depend on the pulse shaping in the signal processing electronics, so the choice of the shaping time is critical (see Sec. 31.8).

A smaller bandgap would produce a larger signal and improve energy resolution, but the intrinsic resistance of the material is critical. Thermal excitation, given by the Fermi-Dirac distribution, promotes electrons into the conduction band, so the thermally excited carrier concentration increases exponentially with decreasing bandgaps. In pure Si the carrier concentration is $\sim 10^{10} \text{cm}^{-3}$ at 300 K, corresponding to a resistivity $\rho \approx 400\,\mathrm{k}\Omega\,\mathrm{cm}$. In reality, crystal imperfections and minute impurity concentrations limit Si carrier concentrations to $\sim 10^{11}~{\rm cm}^{-3}$ at 300 K, corresponding to a resistivity $\rho \approx 40\,{\rm k}\Omega\,{\rm cm}.$ In practice, resistivities up to $20 \,\mathrm{k}\Omega\,\mathrm{cm}$ are available, with mass production ranging from 5 to $10 \,\mathrm{k}\Omega\,\mathrm{cm}$. Signal currents at keV scale energies are of order μ A. However, for a resistivity of $10^4~\Omega cm$ a 300 μ m thick sensor with 1 cm² area would have a resistance of $300\,\Omega$, so 30 V would lead to a current flow of 100 mA and a power dissipation of 3 W. On the other hand, high-quality single crystals of Si and Ge can be grown economically with suitably large volumes. so to mitigate the effect of resistivity one resorts to reverse-biased diode structures. Although this reduces the bias current relative to a resistive material, the thermally excited leakage current can still be excessive at room temperature, so Ge diodes are typically operated at liquid nitrogen temperature (77 K).

A major effort is to find high-Z materials with a bandgap that is sufficiently high to allow room-temperature operation while still providing good energy resolution. Compound semiconductors, e.g., CdZnTe, can allow this, but typically suffer from charge collection problems, characterized by the product $\mu\tau$ of mobility and carrier lifetime. In Si and Ge $\mu\tau > 1\,\mathrm{cm}^2\,\mathrm{V}^{-1}$ for both electrons and holes, whereas in compound semiconductors it is in the range 10^{-3} – 10^{-8} . Since for holes $\mu\tau$ is typically an order of magnitude smaller than for electrons, detector configurations where the electron contribution to the charge signal dominates—e.g., strip or pixel structures—can provide better performance.

31.7.2. Detector Configurations:

A p-n junction operated at reverse bias forms a sensitive region depleted of mobile charge and sets up an electric field that sweeps charge liberated by radiation to the electrodes. Detectors typically use an asymmetric structure, e.g., a highly doped p electrode and a lightly doped n region, so that the depletion region extends predominantly into the lightly doped volume.

In a planar device the thickness of the depleted region is

$$W = \sqrt{2\epsilon (V + V_{bi})/Ne} = \sqrt{2\rho\mu\epsilon(V + V_{bi})}, \qquad (31.18)$$

where V = external bias voltage

 V_{bi} = "built-in" voltage ($\approx 0.5 \text{ V}$ for resistivities typically used in Si detectors)

N =doping concentration

e = electronic charge

 $\epsilon = \text{dielectric constant} = 11.9 \ \epsilon_0 \approx 1 \ \text{pF/cm} \ \text{in Si}$

 $\rho = \text{resistivity (typically 1-10 k}\Omega \text{ cm in Si)}$

 $\mu = \text{charge carrier mobility}$

 $= 1350 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1} \text{ for electrons in Si}$ $= 450 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1} \text{ for holes in Si}$

In Si

$$W=0.5~\left[\mu\mathrm{m}/\sqrt{\Omega\text{-cm}\cdot\mathrm{V}}\right]\times\sqrt{\rho(V+V_{bi})}~\mathrm{for}~n\text{-type Si, and}$$

$$W = 0.3 \ [\mu \text{m}/\sqrt{\Omega \cdot \text{cm} \cdot \text{V}}] \times \sqrt{\rho (V + V_{bi})} \text{ for } p\text{-type Si.}$$

The conductive p and n regions together with the depleted volume form a capacitor with the capacitance per unit area

$$C = \epsilon/W \approx 1 \,[\text{pF/cm}]/W \text{ in Si.}$$
 (31.19)

In strip and pixel detectors the capacitance is dominated by the fringing capacitance. For example, the strip-to-strip Si fringing capacitance is $\sim 1-1.5 \text{ pF cm}^{-1}$ of strip length at a strip pitch of Large volume ($\sim 10^2-10^3~{\rm cm}^3$) Ge detectors are commonly configured as coaxial detectors, e.g., a cylindrical n-type crystal with 5–10 cm diameter and 10 cm length with an inner 5–10 mm diameter n⁺ electrode and an outer p⁺ layer forming the diode junction. Ge can be grown with very low impurity levels, $10^9-10^{10}~{\rm cm}^{-3}$ (HPGe), so these large volumes can be depleted with several kV.

31.7.3. Signal Formation:

The signal pulse shape depends on the instantaneous carrier velocity $v(x)=\mu E(x)$ and the electrode geometry, which determines the distribution of induced charge (e.g., see Ref. 115, pp. 71–83). Charge collection time decreases with increasing bias voltage, and can be reduced further by operating the detector with "overbias," i.e., a bias voltage exceeding the value required to fully deplete the device. The collection time is limited by velocity saturation at high fields (in Si approaching 10^7 cm/s at $E>10^4$ V/cm); at an average field of 10^4 V/cm the collection time is about 15 ps/ μ m for electrons and 10^9 ps/ μ m for holes. In typical fully-depleted detectors 10^9 m thick, electrons are collected within about 10^9 ns, and holes within about 10^9 ns.

Position resolution is limited by transverse diffusion during charge collection (typically 5 μ m for 300 μ m thickness) and by knock-on electrons. Resolutions of 2–4 μ m (rms) have been obtained in beam tests. In magnetic fields, the Lorentz drift deflects the electron and hole trajectories and the detector must be tilted to reduce spatial spreading (see "Hall effect" in semiconductor textbooks).

Electrodes can be in the form of cm-scale pads, strips, or μ m-scale pixels. Various readout structures have been developed for pixels, e.g., CCDs, DEPFETs, monolithic pixel devices that integrate sensor and electronics (MAPS), and hybrid pixel devices that utilize separate sensors and readout ICs connected by two-dimensional arrays of solder bumps. For an overview and further discussion see Ref. 115.

In gamma ray spectroscopy ($E_{\gamma} > 10^2 \text{ keV}$) Compton scattering dominates, so for a significant fraction of events the incident gamma energy is not completely absorbed, i.e., the Compton scattered photon escapes from the detector and the energy deposited by the Compton electron is only a fraction of the total. Distinguishing multi-interaction events, e.g., multiple Compton scatters with a final photoelectric absorption, from single Compton scatters allows background suppression. Since the individual interactions take place in different parts of the detector volume, these events can be distinguished by segmenting the outer electrode of a coaxial detector and analyzing the current pulse shapes. The different collection times can be made more distinguishable by using "point" electrodes, where most of the signal is induced when charges are close to the electrode, similarly to strip or pixel detectors. Charge clusters arriving from different positions in the detector will arrive at different times and produce current pulses whose major components are separated in time. Point electrodes also reduce the electrode capacitance, which reduces electronic noise, but careful design is necessary to avoid low-field regions in the detector volume.

31.7.4. *Radiation Damage*: Radiation damage occurs through two basic mechanisms:

- 1. Bulk damage due to displacement of atoms from their lattice sites. This leads to increased leakage current, carrier trapping, and build-up of space charge that changes the required operating voltage. Displacement damage depends on the nonionizing energy loss and the energy imparted to the recoil atoms, which can initiate a chain of subsequent displacements, i.e., damage clusters. Hence, it is critical to consider both particle type and energy.
- 2. Surface damage due to charge build-up in surface layers, which leads to increased surface leakage currents. In strip detectors the inter-strip isolation is affected. The effects of charge build-up are strongly dependent on the device structure and on fabrication details. Since the damage is proportional to the absorbed energy (when ionization dominates), the dose can be specified in rad (or Gray) independent of particle type.

The increase in reverse bias current due to bulk damage is $\Delta I_r = \alpha \Phi$ per unit volume, where Φ is the particle fluence and α the damage coefficient ($\alpha \approx 3 \times 10^{-17}$ A/cm for minimum ionizing protons

and pions after long-term annealing; $\alpha \approx 2 \times 10^{-17}$ A/cm for 1 MeV neutrons). The reverse bias current depends strongly on temperature

$$\frac{I_R(T_2)}{I_R(T_1)} = \left(\frac{T_2}{T_1}\right)^2 \exp\left[-\frac{E}{2k} \left(\frac{T_1 - T_2}{T_1 T_2}\right)\right] , \qquad (31.20)$$

where E=1.2 eV, so rather modest cooling can reduce the current substantially (\sim 6-fold current reduction in cooling from room temperature to 0°C).

Displacement damage forms acceptor-like states. These trap electrons, building up a negative space charge, which in turn requires an increase in the applied voltage to sweep signal charge through the detector thickness. This has the same effect as a change in resistivity, i.e., the required voltage drops initially with fluence, until the positive and negative space charge balance and very little voltage is required to collect all signal charge. At larger fluences the negative space charge dominates, and the required operating voltage increases $(V \propto N)$. The safe limit on operating voltage ultimately limits the detector lifetime. Strip detectors specifically designed for high voltages have been extensively operated at bias voltages >500 V. Since the effect of radiation damage depends on the electronic activity of defects, various techniques have been applied to neutralize the damage sites. For example, additional doping with oxygen can increase the allowable charged hadron fluence roughly three-fold [117]. Detectors with columnar electrodes normal to the surface can also extend operational lifetime [118]. The increase in leakage current with fluence, on the other hand, appears to be unaffected by resistivity and whether the material is n or p-type. At fluences beyond $10^{15}~\mathrm{cm}^{-2}$ decreased carrier lifetime becomes critical [119,120].

Strip and pixel detectors have remained functional at fluences beyond $10^{15} \,\mathrm{cm}^{-2}$ for minimum ionizing protons. At this damage level, charge loss due to recombination and trapping becomes significant and the high signal-to-noise ratio obtainable with lowcapacitance pixel structures extends detector lifetime. The higher mobility of electrons makes them less sensitive to carrier lifetime than holes, so detector configurations that emphasize the electron contribution to the charge signal are advantageous, e.g., n⁺ strips or pixels on a p- or n-substrate. The occupancy of the defect charge states is strongly temperature dependent; competing processes can increase or decrease the required operating voltage. It is critical to choose the operating temperature judiciously $(-10 \text{ to } 0^{\circ}\text{C} \text{ in typical})$ collider detectors) and limit warm-up periods during maintenance. For a more detailed summary see Ref. 121 and and the web-sites of the ROSE and RD50 collaborations at http://RD48.web.cern.ch/rd48 and http://RD50.web.cern.ch/rd50. Materials engineering, e.g., introducing oxygen interstitials, can improve certain aspects and is under investigation. At high fluences diamond is an alternative, but operates as an insulator rather than a reverse-biased diode.

Currently, the lifetime of detector systems is still limited by the detectors; in the electronics use of standard "deep submicron" CMOS fabrication processes with appropriately designed circuitry has increased the radiation resistance to fluences $> 10^{15}~{\rm cm}^{-2}$ of minimum ionizing protons or pions. For a comprehensive discussion of radiation effects see Ref. 122.

31.8. Low-noise electronics

Revised August 2011 by H. Spieler.

Many detectors rely critically on low-noise electronics, either to improve energy resolution or to allow a low detection threshold. A typical detector front-end is shown in Fig. 31.18.

The detector is represented by a capacitance C_d , a relevant model for most detectors. Bias voltage is applied through resistor R_b and the signal is coupled to the preamplifier through a blocking capacitor C_c . The series resistance R_s represents the sum of all resistances present in the input signal path, e.g. the electrode resistance, any input protection networks, and parasitic resistances in the input transistor. The preamplifier provides gain and feeds a pulse shaper, which tailors the overall frequency response to optimize signal-to-noise ratio while limiting the duration of the signal pulse to accommodate the signal pulse rate. Even if not explicitly stated, all amplifiers provide some form of pulse shaping due to their limited frequency response.

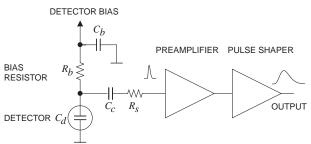

Figure 31.18: Typical detector front-end circuit.

The equivalent circuit for the noise analysis (Fig. 31.19) includes both current and voltage noise sources. The leakage current of a semiconductor detector, for example, fluctuates due to electron emission statistics. The statistical fluctuations in the charge measurement will scale with the square root of the total number of recorded charges, so this noise contribution increases with the width of the shaped output pulse. This "shot noise" i_{nd} is represented by a current noise generator in parallel with the detector. Resistors exhibit noise due to thermal velocity fluctuations of the charge carriers. This yields a constant noise power density vs. frequency, so increasing the bandwidth of the shaped output pulse, i.e. reducing the shaping time, will increase the noise. This noise source can be modeled either as a voltage or current generator. Generally, resistors shunting the input act as noise current sources and resistors in series with the input act as noise voltage sources (which is why some in the detector community refer to current and voltage noise as "parallel" and "series" noise). Since the bias resistor effectively shunts the input, as the capacitor C_b passes current fluctuations to ground, it acts as a current generator i_{nb} and its noise current has the same effect as the shot noise current from the detector. Any other shunt resistances can be incorporated in the same way. Conversely, the series resistor R_s acts as a voltage generator. The electronic noise of the amplifier is described fully by a combination of voltage and current sources at its input, shown as e_{na} and i_{na} .

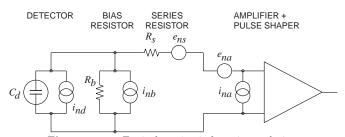

Figure 31.19: Equivalent circuit for noise analysis.

Shot noise and thermal noise have a "white" frequency distribution, i.e. the spectral power densities $dP_n/df \propto di_n^2/df \propto de_n^2/df$ are constant with the magnitudes

$$i_{nd}^2 = 2eI_d$$
,
 $i_{nb}^2 = \frac{4kT}{R_b}$,
 $e_{ns}^2 = 4kTR_s$, (31.21)

where e is the electronic charge, I_d the detector bias current, k the Boltzmann constant and T the temperature. Typical amplifier noise parameters e_{na} and i_{na} are of order nV/ $\sqrt{\rm Hz}$ and pA/ $\sqrt{\rm Hz}$. Trapping and detrapping processes in resistors, dielectrics and semiconductors can introduce additional fluctuations whose noise power frequently exhibits a 1/f spectrum. The spectral density of the 1/f noise voltage is

$$e_{nf}^2 = \frac{A_f}{f}$$
, (31.22)

where the noise coefficient A_f is device specific and of order 10^{-10} – 10^{-12} V².

A fraction of the noise current flows through the detector capacitance, resulting in a frequency-dependent noise voltage $i_n/(\omega C_d)$, which is added to the noise voltage in the input circuit. Thus, the current noise contribution increases with lowering frequency, so its contribution increases with shaping pulse width. Since the individual noise contributions are random and uncorrelated, they add in quadrature. The total noise at the output of the pulse shaper is obtained by integrating over the full bandwidth of the system. Superimposed on repetitive detector signal pulses of constant magnitude, purely random noise produces a Gaussian signal distribution.

Since radiation detectors typically convert the deposited energy into charge, the system's noise level is conveniently expressed as an equivalent noise charge Q_n , which is equal to the detector signal that yields a signal-to-noise ratio of one. The equivalent noise charge is commonly expressed in Coulombs, the corresponding number of electrons, or the equivalent deposited energy (eV). For a capacitive sensor

$$Q_n^2 = i_n^2 F_i T_S + e_n^2 F_v \frac{C^2}{T_S} + F_{vf} A_f C^2 , \qquad (31.23)$$

where C is the sum of all capacitances shunting the input, F_i , F_v , and F_{vf} depend on the shape of the pulse determined by the shaper and T_s is a characteristic time, for example, the peaking time of a semi-gaussian pulse or the sampling interval in a correlated double sampler. The form factors F_i , F_v are easily calculated

$$F_i = \frac{1}{2T_S} \int_{-\infty}^{\infty} [W(t)]^2 dt$$
, $F_v = \frac{T_S}{2} \int_{-\infty}^{\infty} \left[\frac{dW(t)}{dt} \right]^2 dt$, (31.24)

where for time-invariant pulse-shaping W(t) is simply the system's impulse response (the output signal seen on an oscilloscope) for a short input pulse with the peak output signal normalized to unity. For more details see Refs. 123 and 124.

A pulse shaper formed by a single differentiator and integrator with equal time constants has $F_i = F_v = 0.9$ and $F_{vf} = 4$, independent of the shaping time constant. The overall noise bandwidth, however, depends on the time constant, i.e. the characteristic time T_s . The contribution from noise currents increases with shaping time, i.e., pulse duration, whereas the voltage noise decreases with increasing shaping time. Noise with a 1/f spectrum depends only on the ratio of upper to lower cutoff frequencies (integrator to differentiator time constants), so for a given shaper topology the 1/f contribution to Q_n is independent of T_s . Furthermore, the contribution of noise voltage sources to Q_n increases with detector capacitance. Pulse shapers can be designed to reduce the effect of current noise, e.g., mitigate radiation damage. Increasing pulse symmetry tends to decrease F_i and increase F_v (e.g., to 0.45 and 1.0 for a shaper with one CRdifferentiator and four cascaded integrators). For the circuit shown in Fig. 31.19,

$$Q_n^2 = \left(2eI_d + 4kT/R_b + i_{na}^2\right)F_iT_S + \left(4kTR_s + e_{na}^2\right)F_vC_d^2/T_S + F_{vf}A_fC_d^2.$$
(31.25)

As the characteristic time T_S is changed, the total noise goes through a minimum, where the current and voltage contributions are equal. Fig. 31.20 shows a typical example. At short shaping times the voltage noise dominates, whereas at long shaping times the current noise takes over. The noise minimum is flattened by the presence of 1/f noise. Increasing the detector capacitance will increase the voltage noise and shift the noise minimum to longer shaping times.

For quick estimates, one can use the following equation, which assumes an FET amplifier (negligible i_{na}) and a simple CR-RC shaper with time constants τ (equal to the peaking time):

$$(Q_n/e)^2 = 12 \left[\frac{1}{\text{nA} \cdot \text{ns}} \right] I_{d\tau} + 6 \times 10^5 \left[\frac{\text{k}\Omega}{\text{ns}} \right] \frac{\tau}{R_b} + 3.6 \times 10^4 \left[\frac{\text{ns}}{(\text{pF})^2 (\text{nV})^2 / \text{Hz}} \right] e_n^2 \frac{C^2}{\tau} .$$
(31.26)

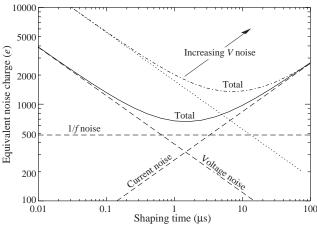

Figure 31.20: Equivalent noise charge vs shaping time. Changing the voltage or current noise contribution shifts the noise minimum. Increased voltage noise is shown as an example.

Noise is improved by reducing the detector capacitance and leakage current, judiciously selecting all resistances in the input circuit, and choosing the optimum shaping time constant.

The noise parameters of the amplifier depend primarily on the input device. In field effect transistors, the noise current contribution is very small, so reducing the detector leakage current and increasing the bias resistance will allow long shaping times with correspondingly lower noise. In bipolar transistors, the base current sets a lower bound on the noise current, so these devices are best at short shaping times. In special cases where the noise of a transistor scales with geometry, i.e., decreasing noise voltage with increasing input capacitance, the lowest noise is obtained when the input capacitance of the transistor is equal to the detector capacitance, albeit at the expense of power dissipation. Capacitive matching is useful with field-effect transistors, but not bipolar transistors. In bipolar transistors, the minimum obtainable noise is independent of shaping time, but only at the optimum collector current I_C , which does depend on shaping time.

$$Q_{n,\mathrm{min}}^2 = 4kT\frac{C}{\sqrt{\beta_{DC}}}\sqrt{F_iF_v} \ \ \mathrm{at} \ \ I_c = \frac{kT}{e}C\sqrt{\beta_{DC}}\sqrt{\frac{F_v}{F_i}}\frac{1}{T_S} \ , \ \ (31.27)$$

where β_{DC} is the DC current gain. For a CR--RC shaper and $\beta_{DC}=100,$

$$Q_{n,\min}/e \approx 250\sqrt{C/\mathrm{pF}}$$
 . (31.28)

Practical noise levels range from $\sim 1e$ for CCD's at long shaping times to $\sim 10^4~e$ in high-capacitance liquid argon calorimeters. Silicon strip detectors typically operate at $\sim 10^3$ electrons, whereas pixel detectors with fast readout provide noise of several hundred electrons.

In timing measurements, the slope-to-noise ratio must be optimized, rather than the signal-to-noise ratio alone, so the rise time t_r of the pulse is important. The "jitter" σ_t of the timing distribution is

$$\sigma_t = \frac{\sigma_n}{(dS/dt)_{S_T}} \approx \frac{t_r}{S/N} , \qquad (31.29)$$

where σ_n is the rms noise and the derivative of the signal dS/dt is evaluated at the trigger level S_T . To increase dS/dt without incurring excessive noise, the amplifier bandwidth should match the rise-time of the detector signal. The 10 to 90% rise time of an amplifier with bandwidth f_U is $0.35/f_U$. For example, an oscilloscope with 350 MHz bandwidth has a 1 ns rise time. When amplifiers are cascaded, which is invariably necessary, the individual rise times add in quadrature.

$$t_r \approx \sqrt{t_{r1}^2 + t_{r2}^2 + \dots + t_{rn}^2} \ . \tag{31.30}$$

Increasing signal-to-noise ratio also improves time resolution, so minimizing the total capacitance at the input is also important. At high signal-to-noise ratios, the time jitter can be much smaller than the rise time. The timing distribution may shift with signal

level ("walk"), but this can be corrected by various means, either in hardware or software [8].

The basic principles discussed above apply to both analog and digital signal processing. In digital signal processing the pulse shaper shown in Fig. 31.18 is replaced by an analog to digital converter (ADC) followed by a digital processor that determines the pulse shape. Digital signal processing allows great flexibility in implementing filtering functions. The software can be changed readily to adapt to a wide variety of operating conditions and it is possible to implement filters that are impractical or even impossible using analog circuitry. However, this comes at the expense of increased circuit complexity and increased demands on the ADC compared to analog shaping.

If the sampling rate of the ADC is too low, high frequency components will be transferred to lower frequencies ("aliasing"). The sampling rate of the ADC must be high enough to capture the maximum frequency component of the input signal. Apart from missing information on the fast components of the pulse, undersampling introduces spurious artifacts. If the frequency range of the input signal is much greater, the noise at the higher frequencies will be transferred to lower frequencies and increase the noise level in the frequency range of pulses formed in the subsequent digital shaper. The Nyquist criterion states that the sampling frequency must be at least twice the maximum relevant input frequency. This requires that the bandwith of the circuitry preceding the ADC must be limited. The most reliable technique is to insert a low-pass filter.

The digitization process also introduces inherent noise, since the voltage range ΔV corresponding to a minimum bit introduces quasi-random fluctuations relative to the exact amplitude

$$\sigma_n = \frac{\Delta V}{\sqrt{12}} \ . \tag{31.31}$$

When the Nyquist condition is fulfilled the noise bandwidth Δf_n is spread nearly uniformly and extends to 1/2 the sampling frequency f_S , so the spectral noise density

$$e_n = \frac{\sigma_n}{\sqrt{\Delta f_n}} = \frac{\Delta V}{\sqrt{12}} \cdot \frac{1}{\sqrt{f_S/2}} = \frac{\Delta V}{\sqrt{6f_S}} . \tag{31.32}$$

Sampling at a higher frequency spreads the total noise over a larger frequency range, so oversampling can be used to increase the effective resolution. In practice, this quantization noise is increased by differential nonlinearity. Furthermore, the equivalent input noise of ADCs is often rather high, so the overall gain of the stages preceding the ADC must be sufficiently large for the preamplifier input noise to override.

When implemented properly, digital signal processing provides significant advantages in systems where the shape of detector signal pulses changes greatly, for example in large semiconductor detectors for gamma rays or in gaseous detectors (e.g. TPCs) where the duration of the current pulse varies with drift time, which can range over orders of magnitude. Where is analog signal processing best (most efficient)? In systems that require fast time response the high power requirements of high-speed ADCs are prohibitive. Systems that are not sensitive to pulse shape can use fixed shaper constants and rather simple filters, which can be either continuous or sampled. In high density systems that require small circuit area and low power (e.g. strip and pixel detectors), analog filtering often yields the required response and tends to be most efficient.

For a more detailed introduction to detector signal processing and electronics see Ref. 115.

31.9. Calorimeters

A calorimeter is designed to measure the energy deposition and its direction for a contained electromagnetic (EM) or hadronic shower. The characteristic interaction distance for an electromagnetic interaction is the radiation length X_0 , which ranges from 13.8 g cm⁻² in iron to 6.0 g $\rm cm^{-2}$ in uranium.* Similarly, the characteristic nuclear interaction length λ_I varies from 132.1 g cm⁻² (Fe) to 209 g cm⁻² (U). In either case, a calorimeter must be many interaction lengths deep, where "many" is determined by physical size, cost, and other factors. EM calorimeters tend to be 15–30 X_0 deep, while hadronic calorimeters are usually compromised at 5–8 λ_I . In real experiments there is likely to be an EM calorimeter in front of the hadronic section, which in turn has less sampling density in the back, so the hadronic cascade occurs in a succession of different structures.

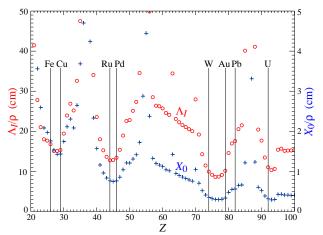

Figure 31.21: Nuclear interaction length λ_I/ρ (circles) and radiation length X_0/ρ (+'s) in cm for the chemical elements with Z > 20 and $\lambda_I < 50$ cm.

In all cases there is a premium on small λ_I/ρ and X_0/ρ (both with units of length). These quantities are shown for Z>20 for the chemical elements in Fig. 31.21. For the hadronic case, metallic absorbers in the W-Au region are best, followed by U. The Ru-Pd region elements are rare and expensive. Lead is a bad choice. Given cost considerations, Fe and Cu might be appropriate choices. For EM calorimeters high Z is preferred, and lead is not a bad choice.

These considerations are for sampling calorimeters consisting of metallic absorber sandwiched or (threaded) with an active material which generates signal. The active medium may be a scintillator, an ionizing noble liquid, a gas chamber, a semiconductor, or a Cherenkov radiator. The average interaction length is thus greater than that of the absorber alone, sometimes substantially so.

There are also homogeneous calorimeters, in which the entire volume is sensitive, i.e., contributes signal. Homogeneous calorimeters (so far usually electromagnetic) may be built with inorganic heavy (high density, high $\langle Z \rangle$) scintillating crystals, or non-scintillating Cherenkov radiators such as lead glass and lead fluoride. Scintillation light and/or ionization in noble liquids can be detected. Nuclear interaction lengths in inorganic crystals range from 17.8 cm (LuAlO₃) to 42.2 cm (NaI). Popular choices have been BGO with $\lambda_I = 22.3$ cm and $X_0 = 1.12 \,\mathrm{cm}$, and PbWO₄ (20.3 cm and 0.89 cm). Properties of these and other commonly used inorganic crystal scintillators can be found in Table 31.4.

31.9.1. Electromagnetic calorimeters:

Revised October 2009 by R.-Y. Zhu (California Inst. of Technology).

The development of electromagnetic showers is discussed in the section on "Passage of Particles Through Matter" (Sec. 30 of this Review).

Formulae are given which approximately describe average showers, but since the physics of electromagnetic showers is well understood, detailed and reliable Monte Carlo simulation is possible. EGS4 [125] and GEANT [126] have emerged as the standards.

There are homogeneous and sampling electromagnetic calorimeters. In a homogeneous calorimeter the entire volume is sensitive, i.e., contributes signal. Homogeneous electromagnetic calorimeters may be built with inorganic heavy (high-Z) scintillating crystals such as BGO, CsI, NaI, and PWO, non-scintillating Cherenkov radiators such as lead glass and lead fluoride, or ionizing noble liquids. Properties of commonly used inorganic crystal scintillators can be found in Table 31.4. A sampling calorimeter consists of an active medium which generates signal and a passive medium which functions as an absorber. The active medium may be a scintillator, an ionizing noble liquid, a gas chamber, or a semiconductor. The passive medium is usually a material of high density, such as lead, iron, copper, or depleted uranium.

The energy resolution σ_E/E of a calorimeter can be parametrized as $a/\sqrt{E} \oplus b \oplus c/E$, where \oplus represents addition in quadrature and E is in GeV. The stochastic term a represents statistics-related fluctuations such as intrinsic shower fluctuations, photoelectron statistics, dead material at the front of the calorimeter, and sampling fluctuations. For a fixed number of radiation lengths, the stochastic term a for a sampling calorimeter is expected to be proportional to $\sqrt{t/f}$, where t is plate thickness and f is sampling fraction [127,128]. While a is at a few percent level for a homogeneous calorimeter, it is typically 10% for sampling calorimeters. The main contributions to the systematic, or constant, term b are detector non-uniformity and calibration uncertainty. In the case of the hadronic cascades discussed below, non-compensation also contributes to the constant term. One additional contribution to the constant term for calorimeters built for modern high-energy physics experiments, operated in a high-beam intensity environment, is radiation damage of the active medium. This can be minimized by developing radiation-hard active media [48] and by frequent in situ calibration and monitoring [47,128]. With effort, the constant term b can be reduced to below one percent. The term c is due to electronic noise summed over readout channels within a few Molière radii. The best energy resolution for electromagnetic shower measurement is obtained in total absorption homogeneous calorimeters, e.g. calorimeters built with heavy crystal scintillators. These are used when ultimate performance is pursued.

The position resolution depends on the effective Molière radius and the transverse granularity of the calorimeter. Like the energy resolution, it can be factored as $a/\sqrt{E} \oplus b$, where a is a few to 20 mm and b can be as small as a fraction of mm for a dense calorimeter with fine granularity. Electromagnetic calorimeters may also provide direction measurement for electrons and photons. This is important for photon-related physics when there are uncertainties in event origin, since photons do not leave information in the particle tracking system. Typical photon angular resolution is about 45 $mrad/\sqrt{E}$, which can be provided by implementing longitudinal segmentation [129] for a sampling calorimeter or by adding a preshower detector [130] for a homogeneous calorimeter without longitudinal segmentation.

Novel technologies have been developed for electromagnetic calorimetry. New heavy crystal scintillators, such as PWO and LSO:Ce (see Sec. 31.4), have attracted much attention for homogeneous calorimetry. In some cases, such as PWO, it has received broad applications in high-energy and nuclear physics experiments. The "spaghetti" structure has been developed for sampling calorimetry with scintillating fibers as the sensitive medium. The "accordion" structure has been developed for sampling calorimetry with ionizing noble liquid as the sensitive medium. Table 31.8 provides a brief description of typical electromagnetic calorimeters built recently for high-energy physics experiments. Also listed in this table are calorimeter depths in radiation lengths (X_0) and the achieved energy resolution. Whenever possible, the performance of calorimeters in

^{*} $X_0 = 120 \ \mathrm{g\,cm^{-2}}\ Z^{-2/3}$ to better than 5% for Z > 23. † $\lambda_I = 37.8 \ \mathrm{g\,cm^{-2}}\ A^{0.312}$ to within 0.8% for Z > 15. See pdg.lbl.gov/AtomicNuclearProperties for actual values.

| Table 31.8: | Resolution of typical electromagnetic calorimeters. |
|--------------|-----------------------------------------------------|
| E is in GeV. | |

| ${\it Technology}~({\it Experiment})$ | Depth | Energy resolution | Date |
|-------------------------------------------|---------------------|----------------------------------------------|------|
| NaI(Tl) (Crystal Ball) | $20X_0$ | $2.7\%/\mathrm{E}^{1/4}$ | 1983 |
| $\mathrm{Bi_4Ge_3O_{12}}$ (BGO) (L3) | $22X_0$ | $2\%/\sqrt{E} \oplus 0.7\%$ | 1993 |
| CsI (KTeV) | $27X_0$ | $2\%/\sqrt{E} \oplus 0.45\%$ | 1996 |
| CsI(Tl) (BaBar) | $16-18X_0$ | $2.3\%/E^{1/4} \oplus 1.4\%$ | 1999 |
| CsI(Tl) (BELLE) | $16X_0$ | 1.7% for $E_{\gamma} > 3.5~{\rm GeV}$ | 1998 |
| $PbWO_4$ (PWO) (CMS) | $25X_0$ | $3\%/\sqrt{E} \oplus 0.5\% \oplus 0.2/E$ | 1997 |
| Lead glass (OPAL) | $20.5X_0$ | $5\%/\sqrt{E}$ | 1990 |
| Liquid Kr (NA48) | $27X_0$ | $3.2\%/\sqrt{E} \oplus 0.42\% \oplus 0.09/E$ | 1998 |
| Scintillator/depleted U (ZEUS) | 20-30X ₀ | $18\%/\sqrt{E}$ | 1988 |
| Scintillator/Pb (CDF) | $18X_0$ | $13.5\%/\sqrt{E}$ | 1988 |
| Scintillator fiber/Pb spaghetti (KLOE) | $15X_0$ | $5.7\%/\sqrt{E} \oplus 0.6\%$ | 1995 |
| Liquid Ar/Pb (NA31) | $27X_0$ | $7.5\%/\sqrt{E} \oplus 0.5\% \oplus 0.1/E$ | 1988 |
| Liquid Ar/Pb (SLD) | $21X_0$ | $8\%/\sqrt{E}$ | 1993 |
| Liquid Ar/Pb (H1) | $20 – 30X_0$ | $12\%/\sqrt{E}\oplus 1\%$ | 1998 |
| Liquid Ar/depl. U (DØ) | $20.5X_0$ | $16\%/\sqrt{E} \oplus 0.3\% \oplus 0.3/E$ | 1993 |
| Liquid Ar/Pb accordion (ATLAS) | $25X_0$ | $10\%/\sqrt{E} \oplus 0.4\% \oplus 0.3/E$ | 1996 |

situ is quoted, which is usually in good agreement with prototype test beam results as well as EGS or GEANT simulations, provided that all systematic effects are properly included. Detailed references on detector design and performance can be found in Appendix C of reference [128] and Proceedings of the International Conference series on Calorimetry in Particle Physics.

31.9.2. *Hadronic calorimeters*: [1–5,128] Revised October 2011 by D. E. Groom (LBNL).

A relatively new variant is the detection of Cerenkov light in hadron calorimetry. Such a calorimeter is sensitive to e^{\pm} 's in the EM showers plus a few relativistic pions. An example is the radiation-hard forward calorimeter in CMS, with iron absorber and quartz fiber readout by PMT's.

Ideally the calorimeter is segmented in ϕ and θ (or $\eta = -\ln\tan(\theta/2)$). Fine segmentation, while desirable, is limited by cost, readout complexity, practical geometry, and the transverse size of the cascades—but see [132]. An example, a wedge of the ATLAS central barrel calorimeter, is shown in Fig. 31.22(b).

In an inelastic hadronic collision a significant fraction f_{em} of the energy is removed from further hadronic interaction by the production of secondary π^0 's and η 's, whose decay photons generate high-energy electromagnetic (EM) showers. Charged secondaries (π^{\pm} , p, ...) deposit energy via ionization and excitation, but also interact with

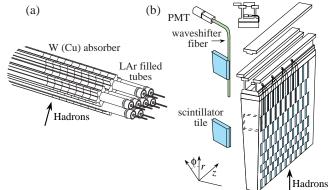

Figure 31.22: (a) ATLAS forward hadronic calorimeter structure (FCal2, 3). Tubes containing LAr are embedded in a mainly tungsten matrix. (b) ATLAS central calorimeter wedge; iron with plastic scintillator tile with wavelength-shifting fiber readout.

nuclei, producing spallation protons and neutrons, evaporation neutrons, and spallation products. The charged collision products produce detectable ionization, as do the showering γ -rays from the prompt de-excitation of highly excited nuclei. The recoiling nuclei generate little or no detectable signal. The neutrons lose kinetic energy in elastic collisions over hundreds of ns, gradually thermalize, and are captured, with the production of more γ -rays—usually outside the acceptance gate of the electronics. Between endothermic spallation losses, nuclear recoils, and late neutron capture, a significant fraction of the hadronic energy (20%–40%, depending on the absorber and energy of the incident particle) is invisible.

In contrast to EM showers, hadronic cascade processes are characterized by the production of relatively few high-energy particles. The lost energy and f_{em} , the $\pi^0 \to \gamma \gamma$ fraction are highly variable from event to event. Until there is event-by-event knowledge of both the invisible energy loss and EM deposit (to be discussed below), the energy resolution of a hadron calorimeter will remain significantly worse than that of an EM calorimeter.

It has been shown by a simple induction argument, and verified by experiment, that the decrease in the average value of the hadronic energy fraction $(\langle f_h \rangle = 1 - \langle f_{em} \rangle)$ as the projectile energy E increases is fairly well described by the power law [133,135]

$$\langle f_h \rangle \approx (E/E_0)^{m-1} \quad \text{(for } E > E_0) , \qquad (31.33)$$

at least up to a few hundred GeV. The exponent m depends logarithmically on the mean multiplicity and the mean fractional loss to π^0 production in a single interaction. It is in the range 0.80–0.87, but must be obtained experimentally for each calorimeter configuration. E_0 is roughly the energy for the onset of inelastic collisions. It is 1 GeV or a little less for incident pions [133].

In a hadron-nucleus collision a large fraction of the incident energy is carried by a "leading particle" with the same quark content as the incident hadron. If the projectile is a charged pion, the leading particle is usually a pion, which can be neutral and hence contributes to the EM sector. This is not true for incident protons. The result is an increased mean hadronic fraction for incident protons: in Eq. (31.34b) $E_0 \approx 2.6~{\rm GeV}~[133,134,136].$

The EM energy deposit is usually detected more efficiently than the hadronic energy deposit. If the detection efficiency for the EM sector is e and that for the hadronic sector is h, then the ratio of the mean response to a pion to that for an electron is

$$\pi/e = \langle f_{em} \rangle + \langle f_h \rangle h/e = 1 - (1 - h/e) \langle f_h \rangle$$

$$\approx 1 - (1 - h/e) (E/E_0)^{m-1} .$$
(31.34a)
$$(31.34b)$$

If $h \neq e$ the hadronic response is not a linear function of energy. Only the product $(1-h/e)E_0^{1-m}$ can be obtained by measuring π/e as a function of energy. Since 1-m is small and $E_0 \approx 1$ GeV for the usual pion-induced cascades, this fact is usually ignored and h/e is reported.

The discussion above assumes an idealized calorimeter, with the same structure throughout and without leakage. "Real" calorimeters

usually have an EM detector in front and a coarse "catcher" in the back. Complete containment is generally impractical.

By definition, $0 \le f_{em} \le 1$. Its variance changes only slowly with energy, but perforce $\langle f_{em} \rangle \to 1$ as the projectile energy increases. An empirical power law $\sigma_{f_{em}} = (E/E_1)^{1-\ell}$ (where $\ell < 1$) describes the energy dependence adequately and has the right asymptotic properties. For $h/e \ne 1$, fluctuations in f_{em} significantly contribute to the resolution, in particular contributing a larger fraction of the variance at high energies. Since the f_{em} distribution has a tail on the high side, the calorimeter response is non-Gaussian with a high-energy tail if h/e < 1. Noncompensation $(h/e \ne 1)$ thus seriously degrades resolution as well as producing a nonlinear response.

It is clearly desirable to *compensate* the response, *i.e.*, to design the calorimeter such that h/e=1. This is possible only with a sampling calorimeter, where several variables can be chosen or tuned:

- 1. Decrease the EM sensitivity. EM cross sections increase with Z,[†] and most of the energy in an EM shower is deposited by low-energy electrons. A disproportionate fraction of the EM energy is thus deposited in the higher-Z absorber. Lower-Z cladding, such as the steel cladding on ZEUS U plates, preferentially absorbs low-energy γ's in EM showers and thus also lowers the electronic response. G10 signal boards in the DØ calorimeters had the same effect. The degree of EM signal suppression can be somewhat controlled by tuning the sensor/absorber thickness ratio.
- 2. Increase the hadronic sensitivity. The abundant neutrons produced in the cascade have a large n-p scattering cross section, with the production of low-energy scattered protons in hydrogenous sampling materials such as butane-filled proportional counters or plastic scintillator. (When scattering from a nucleus with mass number A, a neutron can at most lose $4/(1+A)^2$ of its kinetic energy.) The down side in the scintillator case is that the signal from a highly-ionizing proton stub can be reduced by as much as 90% by recombination and quenching (Birk's Law, Eq. (31.2)).
- 3. Fabjan and Willis proposed that the additional signal generated in the aftermath of fission in ²³⁸U absorber plates should compensate nuclear fluctuations [137]. The production of fission fragments due to fast n capture was later observed [138]. However, while a very large amount of energy is released, it is mostly carried by low-velocity, very highly ionizing fission fragments which produce very little observable signal because of recombination and quenching. The approach seemed promising for awhile. But, for example, much of the compensation observed with the ZEUS ²³⁸U/scintillator calorimeter was mainly the result of methods 2 and 3 above.

Motivated very much by the work of Brau, Gabriel, Brückmann, and Wigmans [139], several groups built calorimeters which were very nearly compensating. The degree of compensation was sensitive to the acceptance gate width, and so could be somewhat further tuned. These included

- a) HELIOS with 2.5 mm thick scintillator plates sandwiched between 2 mm thick $^{238}{\rm U}$ plates (one of several structures); $\sigma/E=0.34/\sqrt{E}$ was obtained,
- b) ZEUS, 2.6 cm thick scintillator plates between 3.3 mm 238 U plates; $\sigma/E = 0.35/\sqrt{E}$,
- c) a ZEUS prototype with 10 mm Pb plates and 2.5 mm scintillator sheets; $\sigma/E = 0.44/\sqrt{E}$, and
- d) DØ, where the sandwich cell consists of a 4–6 mm thick 238 U plate, 2.3 mm LAr, a G-10 signal board, and another 2.3 mm LAr gap. Given geometrical and cost constraints, the calorimeters used in modern collider detectors are not compensating: $h/e \approx 0.7$, for the ATLAS central barrel calorimeter, is typical.

A more versatile approach to compensation is provided by a dual-readout calorimeter, in which the signal is sensed by two readout systems with highly contrasting h/e. Although the concept is more than two decades old [140], it has only recently been implemented by the DREAM collaboration [141]. The test beam calorimeter consisted of copper tubes, each filled with scintillator and quartz fibers. If the two signals Q and S (quartz and scintillator) are both normalized to

[†] The asymptotic pair-production cross section scales roughly as $Z^{0.75}$, and |dE/dx| slowly decreases with increasing Z.

electron response, then for each event Eq. (31.34) takes the form:

$$Q = E[f_{em} + h/e|_{Q}(1 - f_{em})]$$

$$S = E[f_{em} + h/e|_{S}(1 - f_{em})]$$
(31.35)

These equations are linear in 1/E and f_{em} , and are easily solved to obtain estimators of the *corrected* energy and f_{em} for each event. Both are subject to resolution effects, but effects due to fluctuations in f_{em} are eliminated. The solution for the corrected energy is given by [135]:

$$E = \frac{RS - Q}{R - 1}$$
, where $R = \frac{1 - h/e|_Q}{1 - h/e|_S}$ (31.36)

R is the energy-independent slope of the event locus on a plot of Q vs S. It can be found either from the fitted slope or by measuring π/e as a function of E.

Although the usually-dominant contribution of the f_{em} distribution to the resolution can be minimized by compensation or the use of dual calorimetry, there remain significant contributions to the resolution:

- Incomplete corrections for leakage, differences in light collection efficiency, and electronics calibration.
- Readout transducer shot noise (usually photoelectron statistics), plus electronic noise.
- 3. Sampling fluctuations. Only a small part of the energy deposit takes place in the scintillator or other sensor, and that fraction is subject to large fluctuations. This can be as high as $40\%/\sqrt{E}$ (lead/scintillator). It is even greater in the Fe/scint case because of the very small sampling fraction (if the calorimeter is to be compensating), and substantially lower in a U/scint calorimeter. It is obviously zero for a homogeneous calorimeter.
- 4. Intrinisic fluctuations. The many ways ionization can be produced in a hadronic shower have different detection efficiencies and are subject to stochastic fluctuations. In particular, a very large fraction of the hadronic energy (~20% for Fe/scint, ~40% for U/scint) is "invisible," going into nuclear dissociation, thermalized neutrons, etc. The lost fraction depends on readout—it will be greater for a Cherenkov readout, less for a heterogeneous active medium such as organic scintillator.

Except in a sampling calorimeter especially designed for the purpose, sampling and intrinsic resolution contributions cannot be separated. This may have been best studied by Drews $et\ al.\ [142]$, who used a calorimeter in which even- and odd-numbered scintillators were separately read out. Sums and differences of the variances were used to separate sampling and intrinsic contributions.

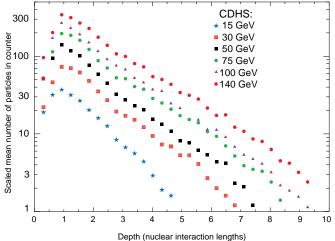

Figure 31.23: Mean profiles of π^+ (mostly) induced cascades in the CDHS neutrino detector [143].

The fractional resolution can be represented by

$$\frac{\sigma}{E} = \frac{a_1(E)}{\sqrt{E}} \oplus \left| 1 - \frac{h}{e} \right| \left(\frac{E}{E_1} \right)^{1-\ell} \tag{31.37}$$

The coefficient a_1 is expected to have mild energy dependence for a number of reasons. For example, the sampling variance is $(\pi/e)E$ rather than E. $(E/E_1)^{1-\ell}$ is the parameterization of σ_{fem} discussed above. At a time when data were of lower quality, a plot of $(\sigma/E)^2$ vs 1/E was apparently well-described by a straight line (constant a_1) with a finite intercept—the square of the right term in Eq. (31.37), then called "the constant term." Modern data show the slight downturn [131].

After the first interaction of the incident hadron, the average longitudinal distribution rises to a smooth peak. The peak position increases slowly with energy. The distribution becomes a reasonably exponential after several interaction length. Examples from the CDHS magnetized iron-scintillator sandwich calorimeter test beam calibration runs [143] are shown in Fig. 31.23. Proton-induced cascades are somewhat shorter and broader than pion-induced cascades [136]. A gamma distribution fairly well describes the longitudinal development of an EM shower, as discussed in Sec. 30.5. Following this logic, Bock et al. suggested that the profile of a hadronic cascade could be fitted by the sum of two gamma distributions, one with a characteristic length X_0 and the other with length λ_I [144]. Fits to this 4-parameter function are commonly used, e.g., by the ATLAS Tilecal collaboration [136]. If the interaction point is not known (the usual case), the distribution must be convoluted with an exponential in the interaction length of the incident particle. Adragna et al. give an analytic form for the convoluted function [136].

The transverse energy deposit is characterized by a central core dominated by EM cascades, together with a wide "skirt" produced by wide-angle hadronic interactions [145].

The CALICE collaboration has tested a "tracking" calorimeter (AHCAL) with highly granular scintillator readout [132]. Since the position of the first interaction is observed, the average longitudinal and radial shower distributions are obtained.

31.9.3. Free electron drift velocities in liquid ionization chambers:

Written August 2009 by W. Walkowiak (U. Siegen)

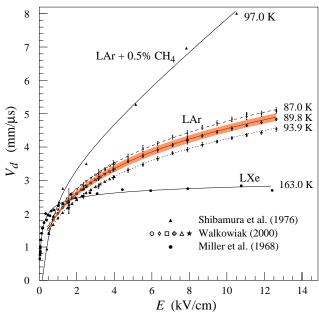

Figure 31.24: Drift velocity of free electrons as a function of electric field strength for LAr [146], LAr + 0.5% CH₄ [148] and LXe [147]. The average temperatures of the liquids are indicated. Results of a fit to an empirical function [152] are superimposed. In case of LAr at 91 K the error band for the global fit [146] including statistical and systematic errors as well as correlations of the data points is given. Only statistical errors are shown for the individual LAr data points.

Drift velocities of free electrons in LAr [146] are given as a function of electric field strength for different temperatures of the medium in

Fig. 31.24. The drift velocites in LAr have been measured using a double-gridded drift chamber with electrons produced by a laser pulse on a gold-plated cathode. The average temperature gradient of the drift velocity of the free electrons in LAr is described [146] by

$$\frac{\Delta v_d}{\Delta T \, v_d} = (-1.72 \pm 0.08) \, \%/\text{K}.$$

Earlier measurements [147–150] used different techniques and show systematic deviations of the drift velocities for free electrons which cannot be explained by the temperature dependence mentioned above.

Drift velocities of free electrons in LXe [148] as a function of electric field strength are also displayed in Fig. 31.24. The drift velocity saturates for |E| > 3 kV/cm, and decreases with increasing temperature for LXe as well as measured e.g. by [151].

The addition of small concentrations of other molecules like N_2 , H_2 and CH_4 in solution to the liquid typically increases the drift velocities of free electrons above the saturation value [148,149], see example for CH_4 admixture to LAr in Fig. 31.24. Therefore, actual drift velocities are critically dependent on even small additions or contaminations.

31.10. Superconducting magnets for collider detectors

Revised September 2011 by A. Yamamoto (KEK); revised October 2001 by R.D. Kephart (FNAL)

31.10.1. Solenoid Magnets: In all cases SI unit are assumed, so that the magnetic field, B, is in Tesla, the stored energy, E, is in joules, the dimensions are in meters, and $\mu_0 = 4\pi \times 10^{-7}$.

The magnetic field (B) in an ideal solenoid with a flux return iron yoke, in which the magnetic field is < 2 T, is given by

$$B = \mu_0 \, n \, I \tag{31.38}$$

where n is the number of turns/meter and I is the current. In an air-core solenoid, the central field is given by

$$B(0,0) = \mu_0 \, n \, I \frac{L}{\sqrt{L^2 + 4R^2}} \,, \tag{31.39}$$

where L is the coil length and R is the coil radius.

In most cases, momentum analysis is made by measuring the circular trajectory of the passing particles according to $p=mv\gamma=q\,rB$, where p is the momentum, m the mass, q the charge, r the bending radius. The sagitta, s, of the trajectory is given by

$$s = q B \ell^2 / 8p , \qquad (31.40)$$

where ℓ is the path length in the magnetic field. In a practical momentum measurement in colliding beam detectors, it is more effective to increase the magnetic volume than the field strength, since

$$dp/p \propto p/B \ell^2 \,\,\,\,(31.41)$$

where ℓ corresponds to the solenoid coil radius R. The energy stored in the magnetic field of any magnet is calculated by integrating B^2 over all space:

$$E = \frac{1}{2\mu_0} \int B^2 dV {31.42}$$

If the coil thin, (which is the case if it is to superconducting coil), then

$$E \approx (B^2/2\mu_0)\pi R^2 L$$
 (31.43)

For a detector in which the calorimetry is outside the aperture of the solenoid, the coil must be thin in terms of radiation and absorption lengths. This usually means that the coil is superconducting and that the vacuum vessel encasing it is of minimum real thickness and fabricated of a material with long radiation length. There are two major contributors to the thickness of a thin solenoid:

| Experiment | Laboratory | B | | Length | Energy | X/X_0 | E/M |
|------------|---------------|------|-------------|--------|----------------|----------|---------|
| | | [T] | [m] | [m] | [MJ] | | [kJ/kg] |
| TOPAZ* | KEK | 1.2 | 1.45 | 5.4 | 20 | 0.70 | 4.3 |

Table 31.9: Progress of superconducting magnets for particle physics detectors.

1) The conductor consisting of the current-carrying superconducting material (usually NbTi/Cu) and the quench protecting stabilizer (usually aluminum) are wound on the inside of a structural support cylinder (usually aluminum also). The coil thickness scales as B^2R , so the thickness in radiation lengths (X_0) is

$$t_{\text{coil}}/X_0 = (R/\sigma_h X_0)(B^2/2\mu_0)$$
, (31.44)

where $t_{\rm coil}$ is the physical thickness of the coil, X_0 the average radiation length of the coil/stabilizer material, and σ_h is the hoop stress in the coil [155]. $B^2/2\mu_0$ is the magnetic pressure. In large detector solenoids, the aluminum stabilizer and support cylinders dominate the thickness; the superconductor (NbTI/Cu) contributes a smaller fraction. The main coil and support cylinder components typically contribute about 2/3 of the total thickness in radiation lengths.

2) Another contribution to the material comes from the outer cylindrical shell of the vacuum vessel. Since this shell is susceptible to buckling collapse, its thickness is determined by the diameter, length and the modulus of the material of which it is fabricated. The outer vacuum shell represents about 1/3 of the total thickness in radiation length.

31.10.2. Properties of collider detector magnets:

The physical dimensions, central field stored energy and thickness in radiation lengths normal to the beam line of the superconducting solenoids associated with the major collider are given in Table 31.9 [154]. Fig. 31.25 shows thickness in radiation lengths as a function of B^2R in various collider detector solenoids.

The ratio of stored energy to cold mass (E/M) is a useful performance measure. It can also be expressed as the ratio of the stress, σ_h , to twice the equivalent density, ρ , in the coil [155]:

$$\frac{E}{M} = \frac{\int (B^2/2\mu_0)dV}{\rho V_{\text{coil}}} \approx \frac{\sigma_h}{2\rho}$$
 (31.45)

The E/M ratio in the coil is approximately equivalent to H,* the enthalpy of the coil, and it determines the average coil temperature rise after energy absorption in a quench:

$$E/M = H(T_2) - H(T_1) \approx H(T_2)$$
 (31.46)

where T_2 is the average coil temperature after the full energy absorption in a quench, and T_1 is the initial temperature. E/M ratios of 5, 10, and 20 kJ/kg correspond to \sim 65, \sim 80, and \sim 100 K, respectively. The E/M ratios of various detector magnets are shown in Fig. 31.26 as a function of total stored energy. One would like the cold mass to be as small as possible to minimize the thickness, but temperature rise during a quench must also be minimized. An E/M ratio as large as 12 kJ/kg is designed into the CMS solenoid, with the possibility that about half of the stored energy can go to an external dump resistor. Thus the coil temperature can be kept below 80 K if the energy extraction system work well. The limit is set by the maximum temperature that the coil design can tolerate during a quench. This maximum local temperature should be <130 K (50 K + 80 K), so that thermal expansion effects in the coil are manageable.

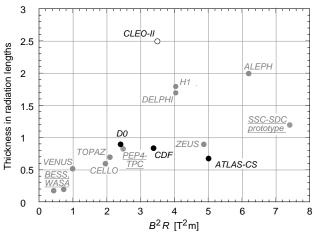

Figure 31.25: Magnet wall thickness in radiation length as a function of B^2R for various detector solenoids. Gray entries are for magnets no longer in use, and entries underlined are not listed in Table 31.9. Open circles are for magnets not designed to be "thin." The SSC-SDC prototype provided important R&D for LHC magnets.

^{*} No longer in service

[†] EM calorimeter is inside solenoid, so small X/X_0 is not a goal

^{*} The enthalpy, or heat content, is called H in the thermodynamics literature. It is not to be confused with the magnetic field intensity B/μ .

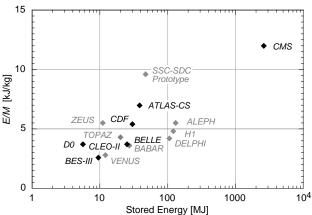

Figure 31.26: Ratio of stored energy to cold mass for major detector solenoids. Gray indicates magnets no longer in operation.

$31.10.3. \quad Toroidal \ magnets:$

Toroidal coils uniquely provide a closed magnetic field without the necessity of an iron flux-return yoke. Because no field exists at the collision point and along the beam line, there is, in principle, no effect on the beam. On the other hand, the field profile generally has 1/r dependence. The particle momentum may be determined by measurements of the deflection angle combined with the sagitta. The deflection (bending) power BL is

$$BL \approx \int_{R_i}^{R_0} \frac{B_i R_i dR}{R \sin \theta} = \frac{B_i R_i}{\sin \theta} \ln(R_0/R_i) , \qquad (31.47)$$

where R_i is the inner coil radius, R_0 is the outer coil radius, and θ is the angle between the particle trajectory and the beam line axis. The momentum resolution given by the deflection may be expressed as

$$\frac{\Delta p}{p} \propto \frac{p}{BL} \approx \frac{p \sin \theta}{B_i R_i \ln(R_0/R_i)} \ . \tag{31.48}$$

The momentum resolution is better in the forward/backward (smaller θ) direction. The geometry has been found to be optimal when $R_0/R_i \approx 3$ –4. In practical designs, the coil is divided into 6–12 lumped coils in order to have reasonable acceptance and accessibility. This causes the coil design to be much more complex. The mechanical structure needs to sustain the decentering force between adjacent coils, and the peak field in the coil is 3–5 times higher than the useful magnetic field for the momentum analysis [153].

31.11. Measurement of particle momenta in a uniform magnetic field [156,157]

The trajectory of a particle with momentum p (in GeV/c) and charge ze in a constant magnetic field \overrightarrow{B} is a helix, with radius of curvature R and pitch angle λ . The radius of curvature and momentum component perpendicular to \overrightarrow{B} are related by

$$p\cos\lambda = 0.3 z B R , \qquad (31.49)$$

where B is in tesla and R is in meters.

The distribution of measurements of the curvature $k\equiv 1/R$ is approximately Gaussian. The curvature error for a large number of uniformly spaced measurements on the trajectory of a charged particle in a uniform magnetic field can be approximated by

$$(\delta k)^2 = (\delta k_{\rm res})^2 + (\delta k_{\rm ms})^2$$
, (31.50)

where $\delta k = \text{curvature error}$

 $\delta k_{\rm res} = {
m curvature\ error\ due\ to\ finite\ measurement\ resolution}$

 $\delta k_{\rm ms} = {\rm curvature~error~due~to~multiple~scattering}.$

If many (≥ 10) uniformly spaced position measurements are made along a trajectory in a uniform medium,

$$\delta k_{\rm res} = \frac{\epsilon}{L'^2} \sqrt{\frac{720}{N+4}} , \qquad (31.51)$$

where N = number of points measured along track

L' = the projected length of the track onto the bending plane

 $\epsilon =$ measurement error for each point, perpendicular to the trajectory.

If a vertex constraint is applied at the origin of the track, the coefficient under the radical becomes 320.

For arbitrary spacing of coordinates s_i measured along the projected trajectory and with variable measurement errors ϵ_i the curvature error $\delta k_{\rm res}$ is calculated from:

$$(\delta k_{\rm res})^2 = \frac{4}{w} \frac{V_{ss}}{V_{ss}V_{s^2s^2} - (V_{ss^2})^2} , \qquad (31.52)$$

where V are covariances defined as $V_{s^ms^n} = \langle s^ms^n \rangle - \langle s^m \rangle \langle s^n \rangle$ with $\langle s^m \rangle = w^{-1} \sum_i (s_i^m/\epsilon_i^2)$ and $w = \sum_i \epsilon_i^{-2}$.

The contribution due to multiple Coulomb scattering is approximately

$$\delta k_{\rm ms} \approx \frac{(0.016)({\rm GeV}/c)z}{Lp\beta\cos^2\lambda} \sqrt{\frac{L}{X_0}} , \qquad (31.53)$$

where p = momentum (GeV/c)

z = charge of incident particle in units of e

 $L={
m the\ total\ track\ length}$

 X_0 = radiation length of the scattering medium (in units of length; the X_0 defined elsewhere must be multiplied by density)

 β = the kinematic variable v/c.

More accurate approximations for multiple scattering may be found in the section on Passage of Particles Through Matter (Sec. 30 of this Review). The contribution to the curvature error is given approximately by $\delta k_{\rm ms} \approx 8 s_{\rm plane}^{\rm rms}/L^2$, where $s_{\rm plane}^{\rm rms}$ is defined there.

32.1. Introduction

Non-accelerator experiments have become increasingly important in particle physics. These include classical cosmic ray experiments, neutrino oscillation measurements, and searches for double-beta decay, dark matter candidates, and magnetic monopoles. The experimental methods are sometimes those familiar at accelerators (plastic scintillators, drift chambers, TRD's, etc.) but there is also instrumentation either not found at accelerators or applied in a radically different way. Examples are atmospheric scintillation detectors (Fly's Eye), massive Cherenkov detectors (Super-Kamiokande, IceCube), ultracold solid state detectors (CDMS). And, except for the cosmic ray detectors, radiologically ultra-pure materials are required.

In this section, some more important detectors special to terrestrial non-accelerator experiments are discussed. Techniques used in both accelerator and non-accelerator experiments are described in Sec. 28, Particle Detectors at Accelerators, some of which have been modified to accommodate the non-accelerator nuances.

Space-based detectors also use some unique instrumentation, but these are beyond the present scope of RPP.

32.2. High-energy cosmic-ray hadron and gammaray detectors

$32.2.1. \quad Atmospheric\ fluorescence\ detectors:$

Updated August 2011 by L.R. Wiencke (Colorado School of Mines).

Cosmic-ray fluorescence detectors (FD) use the atmosphere as a giant calorimeter to measure isotropic scintillation light that traces the development profiles of extensive air showers (EAS). The EASs observed are produced by the interactions of high-energy $(E>10^{17}~{\rm eV})$ subatomic particles in the stratosphere and upper troposphere, independent of the primary species. Experiments with FDs include the pioneering Fly's Eye [1], HiRes [2], the Telescope Array [3], and the Pierre Auger Observatory [4]. The proposed JEM-EUSO [5] FD would tilt down to sweep across a much larger area from space.

The scintillation light is emitted between 290 and 430 nm (Fig. 32.1), when relativistic charged particles, primarily electrons and positrons, excite nitrogen molecules in air, resulting in transitions of the 1P and 2P systems. Reviews and references for the pioneering and ongoing laboratory measurements of fluorescence yield, $Y(\lambda, P, T, u)$, including dependence on wavelength (λ) , temperature (T), pressure (p), and humidity (u) may be found in Refs. 6 and 7.

An FD element (telescope) consists of a non-tracking spherical mirror (3.5–13 m^2 and less than astronomical quality), a close-packed "camera" of PMTs (for example, Hamamatsu R9508 or Photonis XP3062) near the focal plane, and flash ADC readout system with a pulse and track-finding trigger scheme [8]. Simple reflector optics (12° \times 16° degree field of view (FOV) on 256 PMTs) and Schmidt optics (30° \times 30° FOV on 440 PMTs), including a correcting element, have been used. Segmented mirrors have been fabricated from slumped or slumped/polished glass with anodized aluminium coating and from chemically anodized AlMgSiO5 affixed to shaped aluminum. A broadband UV filter (custom fabricated or Schott MUG-6) covers the camera face or much larger entrance aperture to reduce background light such as starlight, airglow, man-made light pollution, and airplane strobelights.

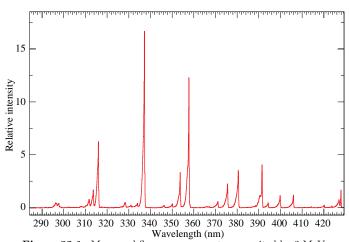

Figure 32.1: Measured fluorescence spectrum excited by 3 MeV electrons in dry air at 800 hPa and 293 K [9].

At $10^{20}\,\mathrm{eV}$, where the flux drops below 1 EAS/km²century, the aperture for an eye of adjacent FD telescopes that span the horizon can reach $10^4~\mathrm{km^2}$ sr. FD operation requires (nearly) moonless nights and clear atmospheric conditions, which imposes a duty cycle of about 10%. Arrangements of LEDs, calibrated diffuse sources [10], pulsed UV

lasers [11], LIDARs* and cloud monitors are used for photometric calibration, atmospheric calibration [12], and determination of exposure [13].

The EAS generates a track consistent with a light source moving at v=c across the FOV. The number of photons (N_{γ}) as a function of atmospheric depth (X) can be expressed as [7]

$$\frac{\mathrm{d}N_{\gamma}}{\mathrm{d}X} = \frac{dE_{\mathrm{dep}}^{\mathrm{tot}}}{dX} \int Y(\lambda, P, T, u) \cdot \tau_{\mathrm{atm}}(\lambda, X) \cdot \varepsilon_{\mathrm{FD}}(\lambda) \mathrm{d}\lambda \quad , \tag{32.1}$$

where $\tau_{atm}(\lambda, X)$ is atmospheric transmission, including wavelength (λ) dependence, and $\varepsilon_{\rm FD}(\lambda)$ is FD efficiency. $\varepsilon_{\rm FD}(\lambda)$ includes geometric factors and collection efficiency of the optics, quantum efficiency of the PMTs, and other throughput factors. The typical systematic uncertainties, Y (10–15%), $\tau_{\rm atm}$ (10%) and $\varepsilon_{\rm FD}$ (photometric calibration 10%), currently dominate the total reconstructed EAS energy uncertainty. $\Delta E/E$ of 20–25% is possible, provided the geometric fit of the EAS axis is constrained by multi-eye stereo projection, or by timing from a colocated sparse array of surface detectors.

Analysis methods to reconstruct the EAS profile and deconvolute the contributions of re-scattered scintillation light, and direct and scattered Cherenkov light are described in [1] and more recently in [14]. The EAS energy is typically obtained by integrating over the Gaisser-Hillas function [15]

$$E_{\rm cal} = \int_0^\infty w_{\rm max} \left(\frac{X-X_0}{X_{\rm max}-X_0}\right)^{(X_{\rm max}-X_0)/\lambda} e^{(X_{\rm max}-X)/\lambda} {\rm d}X \ , \eqno(32.2)$$

where X_{max} is the depth at which the shower reaches its maximum energy deposit w_{max} . X_0 and λ are two shape parameters.

32.2.2. Atmospheric Cherenkov telescopes for high-energy γ -ray astronomy:

Written August 2009 by J. Holder (Bartol Research Inst., Univ. of Delaware).

A wide variety of astrophysical objects are now known to produce high-energy γ -ray photons. Leptonic or hadronic particle populations, accelerated to relativistic energies in the source, produce γ rays typically through inverse Compton boosting of ambient photons, or through the decay of neutral pions produced in hadronic interactions. At energies below ~ 30 GeV, γ -ray emission can be detected directly using satellite or balloon-borne instrumentation, with an effective area approximately equal to the size of the detector (< 1 m²). At higher energies, a technique with much larger effective collection area is required to measure astrophysical γ -ray fluxes, which decrease rapidly with increasing energy. Atmospheric Cherenkov detectors achieve effective collection areas of $\sim 10^5$ m² by employing the Earth's atmosphere as an intrinsic part of the detection technique.

As described in Chapter 26, a hadronic cosmic ray or high energy γ -ray incident on the Earth's atmosphere triggers a particle cascade, or air shower. Relativistic charged particles in the cascade produce Cherenkov radiation, which is emitted along the shower direction, resulting in a light pool on the ground with a radius of ~ 130 m. Cherenkov light is produced throughout the cascade development, with the maximum emission occurring when the number of particles in the cascade is largest, at an altitude of ~ 10 km for primary energies of $100\,\text{GeV}{-}1\,\text{TeV}$. Following absorption and scattering in the atmosphere, the Cherenkov light at ground level peaks at a wavelength, $\lambda \approx 300{-}350$ nm. The photon density is typically ~ 100 photons/m² at 1 TeV, arriving in a brief flash of a few nanoseconds duration. This Cherenkov pulse can be detected from any point within the light pool radius by using large reflecting surfaces to focus the Cherenkov light on to fast photon detectors (Fig. 32.2).

Modern atmospheric Cherenkov telescopes, such as those built and operated by the H.E.S.S. [17], MAGIC [18] and VERITAS [16] collaborations, consist of large (> $100\,\mathrm{m}^2$) segmented mirrors on steerable altitude-azimuth mounts. A camera, made from an array of

up to 1000 photomultiplier tubes (PMTs) covering a field-of-view of up to 5.0° in diameter, is placed at the mirror focus and used to record a Cherenkov image of each air shower. Images are recorded at a rate of a few hundred Hz, the vast majority of which are due to showers with hadronic cosmic-ray primaries. The shape and orientation of the Cherenkov images are used to discriminate γ -ray photon events from this cosmic-ray background, and to reconstruct the photon energy and arrival direction. γ -ray images result from purely electromagnetic cascades and appear as narrow, elongated ellipses in the camera plane. The long axis of the ellipse corresponds to the vertical extension of the air shower, and points back towards the source position in the field-of-view. If multiple telescopes are used to view the same shower ("stereoscopy"), the source position is simply the intersection point of the various image axes. Cosmic-ray primaries produce secondaries with large transverse momenta, which initiate sub-showers. Their images are consequently wider and less regular than those with γ -ray primaries and, since the original charged particle has been deflected by galactic magnetic fields before reaching the Earth, the images have no preferred orientation.

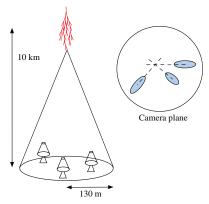

Figure 32.2: A schematic illustration of an atmospheric Cherenkov telescope array. The primary particle initiates an air shower, resulting in a cone of Cherenkov radiation. Telescopes within the Cherenkov light pool record elliptical images; the intersection of the long axes of these images indicates the arrival direction of the primary, and hence the location of a γ -ray source in the sky.

The measurable differences in Cherenkov image orientation and morphology provide the background discrimination which makes ground-based γ -ray astronomy possible. For point-like sources, such as distant Active Galactic Nuclei (AGNs), modern instruments can reject up to 99.999% of the triggered cosmic-ray events, while retaining up to 50% of the γ -ray population. In the case of spatially extended sources, such as Galactic supernova remnants (SNR), the background rejection is less efficient, but the technique can be used to produce γ -ray maps of the emission from the source. The angular resolution depends upon the energy of the primary γ -ray, but is typically 0.1° per event (68% containment radius) at energies above a few hundred GeV.

The total Cherenkov yield from the air shower is proportional to the energy of the primary particle. The image intensity, combined with the reconstructed distance of the shower core from each telescope, can therefore be used to estimate the primary energy. The energy resolution of this technique, also energy-dependent, is typically 15–20% at energies above a few hundred GeV. Energy spectra of γ -ray sources can be measured over a wide range; potentially from ~ 50 GeV to ~ 100 TeV, depending upon the instrument characteristics, source strength, and exposure time. To a first approximation, the lower energy threshold at the trigger level, E_T , depends upon the mirror area, A, the photon collection efficiency, $\eta(\lambda)$, the Cherenkov light yield, $C(\lambda)$, the night sky background light, $B(\lambda)$, the solid angle, Ω , and the trigger resolving time, τ , as follows [19]:

$$E_T \propto \frac{1}{C(\lambda)} \sqrt{\frac{B(\lambda)\Omega\tau}{\eta(\lambda)A}}$$
 (32.3)

^{*} This acronym for "Light Detection and Ranging," refers here to systems that measure atmospheric properties from the light scattered backwards from laser pulses directed into the sky.

In practice, this function may be modified by the properties of the detector; for example, by complex, multi-level, combinatorial trigger systems and highly pixellated fields of view. In addition, the useful scientific threshold, after the application of analysis cuts to select γ -ray events, is always somewhat higher than this.

The first astrophysical source to be convincingly detected using the imaging atmospheric Cherenkov technique was the Crab Nebula [20], with a flux of 2.1×10^{-11} photons cm⁻² s⁻¹ above 1 TeV [21]. Modern arrays have sensitivity sufficient to detect sources with 1% of the Crab Nebula's flux in a few tens of hours, and the TeV source catalog now consists of more than 80 sources. The majority of these have been detected by scanning the Galactic plane from the southern hemisphere with the H.E.S.S. telescope array [22].

32.3. Large neutrino detectors

Large water Cherenkov and scintillator detectors (see Table 32.1) usually consist of a volume of transparent liquid viewed by photomultiplier tubes (PMTs) (see Sec. 31.2); the liquid serves as active target. PMT hit charges and times are recorded and digitized, and triggering is usually based on coincidence of PMTs hits within a time window comparable to the detector's light-crossing time. Because photosensors lining an inner surface represent a driving cost that scales as surface area, very large volumes can be used for comparatively reasonable cost. Some detectors are segmented into subvolumes individually viewed by PMTs, and may include other detector elements (e.g., tracking detectors). Devices to increase light collection, e.g., reflectors or waveshifter plates, may be employed. A common configuration is to have at least one concentric outer layer of liquid material separated from the inner part of the detector to serve as shielding against ambient background. If optically separated and

Table 32.1: Properties of large detectors for rare processes. If total target mass is divided into large submodules, the number of subdetectors is indicated in parentheses.

| Detector | Fid. mass, kton (modules) | PMTs (diameter, cm) | ξ | p.e./MeV | Dates |
|--------------|---------------------------------------|------------------------|-------------------|-----------|-------------|
| Baksan | 0.33, scint (3150) | 1/module (15) | segmented | 40 | 1980- |
| MACRO | 0.6, scint (476) | 2-4/module (20) | segmented | 18 | 1989 - 2000 |
| LVD | 1, scint. (840) | 3/module (15) | segmented | 15 | 1992 - |
| KamLAND | 1, scint | 1325(43)+554(51)* | 34% | 460 | 2002 - |
| Borexino | 0.1, scint | 2212 (20) | 30% | 500 | 2007- |
| SNO+ | 0.78, scint | 9438 (20) | 54% | 400 - 900 | Future |
| CHOOZ | 0.005, scint (Gd) | 192 (20) | 15% | 130 | 1997 - 1998 |
| Double Chooz | 0.020, scint $(Gd)(2)$ | 534/module(20) | 13% | 180 | 2011- |
| Daya Bay | 0.160, scint (Gd)(8) | 192/module (20) | $5.6\%^\dagger$ | 100 | 2011- |
| RENO | 0.030, scint (Gd)(2) | 342/module (25) | 12.6% | 100 | 2011- |

32.3.1. Deep liquid detectors for rare processes:

Revised November 2011 by K. Scholberg & C.W. Walter (Duke University)

Deep, large detectors for rare processes tend to be multi-purpose with physics reach that includes not only solar, reactor, supernova and atmospheric neutrinos, but also searches for baryon number violation, searches for exotic particles such as magnetic monopoles, and neutrino and cosmic ray astrophysics in different energy regimes. The detectors may also serve as targets for long-baseline neutrino beams for neutrino oscillation physics studies. In general, detector design considerations can be divided into high-and low-energy regimes, for which background and event reconstruction issues differ. The high-energy regime, from about 100 MeV to a few hundred GeV, is relevant for proton decay searches, atmospheric neutrinos and high-energy astrophysical neutrinos. The low-energy regime (a few tens of MeV or less) is relevant for supernova, solar, reactor and geological neutrinos.

instrumented with PMTs, an outer layer may also serve as an active veto against entering cosmic rays and other background events. The PMTs for large detectors typically range in size from 20 cm to 50 cm diameter, and typical quantum efficiencies are in the 20-25% range. The active liquid volume requires purification and there may be continuous recirculation of liquid. For large homogeneous detectors, the event interaction vertex is determined using relative timing of PMT hits, and energy deposition is determined from the number of recorded photoelectrons. A "fiducial volume" is usually defined within the full detector volume, some distance away from the PMT array. Inside the fiducial volume, enough PMTs are illuminated per event that reconstruction is considered reliable, and furthermore, entering background from the enclosing walls is suppressed by a buffer of self-shielding. PMT and detector optical parameters are calibrated using laser, LED, or other light sources. Quality of event reconstruction typically depends on photoelectron yield, pixelization and timing.

 $[\]dagger$ The effective Daya Bay coverage is 12% with top and bottom reflectors.

 $[\]ddagger$ The effective Kamiokande III coverage was 25% with light collectors.

 $[\]S$ The effective SNO coverage was 54% with light collectors.

Because in most cases one is searching for rare events, large detectors are usually sited underground to reduce cosmic-ray related background (see Chapter 26). The minimum depth required varies according to the physics goals [23].

32.3.1.1. Liquid scintillator detectors:

Past and current large underground detectors based on hydrocarbon scintillators include LVD, MACRO, Baksan, Borexino, KamLAND and SNO+. Experiments at nuclear reactors include CHOOZ. Double CHOOZ, Daya Bay, and RENO. Organic liquid scintillators (see Sec. 31.3.0) for large detectors are chosen for high light yield and attenuation length, good stability, compatibility with other detector materials, high flash point, low toxicity, appropriate density for mechanical stability, and low cost. They may be doped with waveshifters and stabilizing agents. Popular choices are pseudocumene (1,2,4-trimethylbenzene) with a few g/L of the PPO (2,5-diphenyloxazole) fluor, and linear alkylbenzene (LAB). In a typical detector configuration there will be active or passive regions of undoped scintillator, non-scintillating mineral oil or water surrounding the inner neutrino target volume. A thin vessel or balloon made of nylon, acrylic or other material transparent to scintillation light may contain the inner target; if the scintillator is buoyant with respect to its buffer, ropes may hold the balloon in place. For phototube surface coverages in the 20-40% range, yields in the few hundreds of photoelectrons per MeV of energy deposition can be obtained. Typical energy resolution is about $7\%/\sqrt{E(\text{MeV})}$, and typical position reconstruction resolution is a few tens of cm at ~ 1 MeV, scaling as $\sim N^{-1/2}$, where N is the number of photoelectrons detected.

Shallow detectors for reactor neutrino oscillation experiments require excellent muon veto capabilities. For $\bar{\nu}_e$ detection via inverse beta decay on free protons, $\bar{\nu}_e + p \rightarrow n + e^+$, the neutron is captured by a proton on a ~180 μ s timescale, resulting in a 2.2 MeV γ ray, observable by Compton scattering and which can be used as a tag in coincidence with the positron signal. The positron annihilation γ rays may also contribute. Inverse beta decay tagging may be improved by addition of Gd at ~0.1% by mass, which for natural isotope abundance has a ~49,000 barn cross-section for neutron capture (in contrast to the 0.3 barn cross-section for capture on free protons). Gd capture takes ~30 μ s, and is followed by a cascade of γ rays adding up to about 8 MeV. Gadolinium doping of scintillator requires specialized formulation to ensure adequate attenuation length and stability.

Scintillation detectors have an advantage over water Cherenkov detectors in the lack of Cherenkov threshold and the high light yield. However, scintillation light emission is nearly isotropic, and therefore directional capabilities are relatively weak. Liquid scintillator is especially suitable for detection of low-energy events. Radioactive backgrounds are a serious issue, and include long-lived cosmogenics. To go below a few MeV, very careful selection of materials and purification of the scintillator is required (see Sec. 32.6). Fiducialization and tagging can reduce background. A recent idea, not yet realized, is to dissolve neutrinoless double beta decay $(0\nu\beta\beta)$ isotopes in scintillator (for instance 150 Nd in SNO+). Although energy resolution is poor compared to typical $0\nu\beta\beta$ search experiments, the quantity of isotope could be so large that the kinematic signature of $0\nu\beta\beta$ would be visible as a clear feature in the spectrum.

${\bf 32.3.1.2.} \quad \textit{Water Cherenkov detectors:} \\$

Very large-imaging water detectors reconstruct ten-meter-scale Cherenkov rings produced by charged particles (see Sec. 31.5.0). The first such large detectors were IMB and Kamiokande. The only currently existing instance of this class of detector, with fiducial volume of 22.5 kton and total mass of 50 kton, is Super-Kamiokande (Super-K). For volumes of this scale, absorption and scattering of Cherenkov light are non-negligible, and a wavelength-dependent factor $\exp(-d/L(\lambda))$ (where d is the distance from emission to the sensor and $L(\lambda)$ is the attenuation length of the medium) must be included in the integral of Eq. (31.5) for the photoelectron yield. Attenuation lengths on the order of 100 meters have been achieved.

Cherenkov detectors are excellent electromagnetic calorimeters, and the number of Cherenkov photons produced by an e/γ is nearly proportional to its kinetic energy. For massive particles, the number of photons produced is also related to the energy, but not linearly. For any type of particle, the visible energy $E_{\rm vis}$ is defined as the

energy of an electron which would produce the same number of Cherenkov photons. The number of collected photoelectrons depends on the scattering and attenuation in the water along with the photocathode coverage, quantum efficiency and the optical parameters of any external light collection systems or protective material surrounding them. Event-by-event corrections are made for geometry and attenuation. For a typical case, in water $N_{\rm p.e.} \sim 15 \, \xi \, E_{\rm vis}({\rm MeV})$, where ξ is the effective fractional photosensor coverage. Cherenkov photoelectron yield per MeV of energy is relatively small compared to that for scintillator, e.g., ~ 6 pe/MeV for Super-K with a PMT surface coverage of $\sim 40\%$. In spite of light yield and Cherenkov threshold issues, the intrinsic directionality of Cherenkov light allows individual particle tracks to be reconstructed. Vertex and direction fits are performed using PMT hit charges and times, requiring that the hit pattern be consistent with a Cherenkov ring.

High-energy (~100 MeV or more) neutrinos from the atmosphere or beams interact with nucleons; for the nucleons bound inside the ¹⁶O nucleus, the nuclear effects both at the interaction, and as the particles leave the nucleus must be considered when reconstructing the interaction. Various event topologies can be distinguished by their timing and fit patterns, and by presence or absence of light in a veto. "Fully-contained" events are those for which the neutrino interaction final state particles do not leave the inner part of the detector; these have their energies relatively well measured. Neutrino interactions for which the lepton is not contained in the inner detector sample have higher-energy parent neutrino energy distributions. For example, in "partially-contained" events, the neutrino interacts inside the inner part of the detector but the lepton (almost always a muon, since only muons are penetrating) exits. "Upward-going muons" can arise from neutrinos which interact in the rock below the detector and create muons which enter the detector and either stop, or go all the way through (entering downward-going muons cannot be distinguished from cosmic rays). At high energies, multi-photoelectron hits are likely and the charge collected by each PMT (rather than the number of PMTs firing) must be used; this degrades the energy resolution to approximately $2\%/\sqrt{\xi E_{\text{vis}}(\text{GeV})}$. The absolute energy scale in this regime can be known to $\approx 2-3\%$ using cosmic-ray muon energy deposition, Michel electrons and π^0 from atmospheric neutrino interactions. Typical vertex resolutions for GeV energies are a few tens of cm [24]. Angular resolution for determination of the direction of a charged particle track is a few degrees. For a neutrino interaction, because some final-state particles are usually below Cherenkov threshold, knowledge of direction of the incoming neutrino direction itself is generally worse than that of the lepton direction, and dependent on neutrino energy.

Multiple particles in an interaction (so long as they are above Cherenkov threshold) may be reconstructed, allowing for the exclusive reconstruction of final states. In searches for proton decay, multiple particles can be kinematically reconstructed to form a decaying nucleon. High-quality particle identification is also possible: γ rays and electrons shower, and electrons scatter, which results in fuzzy rings, whereas muons, pions and protons make sharp rings. These patterns can be quantitatively separated with high reliability using maximum likelihood methods [25]. A e/μ misidentification probability of $\sim 0.4\%/\xi$ in the sub-GeV range is consistent with the performance of several experiments for $4\% < \xi < 40\%$. Sources of background for high energy interactions include misidentified cosmic muons and anomalous light patterns when the PMTs sometimes "flash" and emit photons themselves. The latter class of events can be removed using its distinctive PMT signal patterns, which may be repeated. More information about high energy event selection and reconstruction may be found in reference [26].

In spite of the fairly low light yield, large water Cherenkov detectors may be employed for reconstructing low-energy events, down to e.g. \sim 4-5 MeV for Super-K [27]. Low-energy neutrino interactions of solar neutrinos in water are predominantly elastic scattering off atomic electrons; single electron events are then reconstructed. At solar neutrino energies, the visible energy resolution $(\sim 30\%/\sqrt{\xi\,E_{\rm vis}({\rm MeV})})$ is about 20% worse than photoelectron counting statistics would imply. Using an electron LINAC and/or nuclear sources, 0.5–1.5% determination of the absolute energy scale

has been achieved at solar neutrino energies. Angular resolution is limited by multiple scattering in this energy regime (25–30°). At these energies, radioactive backgrounds become a dominant issue. These backgrounds include radon in the water itself or emanated by detector materials, and γ rays from the rock and detector materials. In the few to few tens of MeV range, radioactive products of cosmic ray muon-induced spallation are troublesome, and are removed by proximity in time and space to preceding muons, at some cost in dead time.

The Sudbury Neutrino Observatory (SNO) detector [28] is the only instance of a large heavy water detector and deserves mention here. In addition to an outer 1.7 kton of light water, SNO contained 1 kton of D₂O, giving it unique sensitivity to neutrino neutral current $(\nu_x + d \rightarrow \nu_x + p + n)$, and charged current $(\nu_e + d \rightarrow p + p + e^-)$ deuteron breakup reactions. The neutrons were detected in three ways: In the first phase, via the reaction $n + d \rightarrow t + \gamma + 6.25$ MeV; Cherenkov radiation from electrons Compton-scattered by the γ rays was observed. In the second phase, NaCl was dissolved in the water. 35 Cl captures neutrons, $n + ^{35}$ Cl \rightarrow 36 Cl $+ \gamma + 8.6$ MeV. The γ rays were observed via Compton scattering. In a final phase, specialized low-background 3 He counters ("neutral current detectors" or NCDs) were deployed in the detector. These detected neutrons via $n + ^{3}$ He $\rightarrow p + t + 0.76$ MeV, and ionization charge from energy loss of the products was recorded in proportional counters.

32.3.2. Coherent radio Cherenkov radiation detectors : Written October 2011 by S.R. Klein (LBNL)

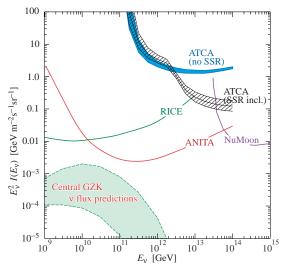

Figure 32.3: Representative ν flux limits from radio-detection experiments, illustrating the energy ranges for different techniques. Shown are limits from the Rice, ANITA, NuMoon and Lunaska (ATCA) collaborations. NuMoon and Lunaska are low and high frequency lunar scans respectively, showing the strengths of the two different frequency bands. The two separate limits for ATCA are for different models of the lunar regolith; their separation is a measure of the resultant uncertainty. Also shown, for comparison is the mid-range of flux predictions for GZK neutrinos from Ref. 34.

Radio detectors sensitive to coherent Cherenkov radiation provide an attractive way to search for ultra-high energy cosmic neutrinos. These neutrinos are the only long-range probe of the ultra-high energy cosmos. Protons and heavier nuclei with energies $\gtrsim 5 \times 10^{19}$ eV are limited to ranges of less than 100 Mpc by interactions with CMB photons (the GZK effect [29]) , and gamma rays pair-produce from the CMB. The decay products of the particles produced in the hadronic interactions include neutrinos. To detect a useful number of these "GZK neutrinos" annually (assuming that ultra-high energy cosmic rays are protons) requires a detector of about 100 km³ in volume. This is too big for an optical Cherenkov detector. Optical attenuation lengths are less than 200 m in ice or water, so a 100 km³ detector would require a prohibitive number of sensors.

Electromagnetic and hadronic showers produce radio pulses via the Askaryan effect [30], as discussed in Sec. 30. The shower contains more electrons than positrons, leading to coherent emission. The electric field strength is proportional to the neutrino energy; the radiated power goes as its square. Detectors with antennas placed in the active volume have thresholds around $10^{17}~{\rm eV}$.

The electric field strength increases linearly with frequency, up to a cut-off wavelength set by the transverse size of the shower. The cut-off is about 1 GHz in ice, and 2.5 GHz in rock/lunar regolith. The broadband spectrum argues for a wide detection bandwidth, but, dispersion during signal transmission can cause technical challenges. The angular distribution depends on the frequency. Near the cutoff frequency, radiation is emitted in a narrow cone, centered around the Cherenov angle (about 56° in ice) [31]. At lower frequencies, the angular distribution broadens, eventually becoming largely isotropic. The signal is linearly polarized in the plane containing the shower direction and the photon direction. This polarization is a useful check that any observed signal is indeed coherent Cherenkov radiation. Polarization measurements can be used to help reconstruct the neutrino direction.

Radiodetection requires a dielectric medium, with a long absorption length for radio waves. The huge target volumes require that this be a commonly available natural material, usually Antarctic ice or the lunar regolith [32].

When viewed from near the Cherenkov angle, the experimental signal is a short wideband radio pulse coming from a shower-sized region within a solid. The initial pulse width is ≈ 1 ns, but it may be broadened by dispersion as it propagates. As long as the dispersion can be accounted for, a large bandwidth detector is the most sensitive. Because the angular distribution depends on the frequency, spectral information can be used to help reconstruct the neutrino direction.

Radio detectors have observed cosmic-ray air showers in the atmosphere. The physics of radio-wave generation in air showers is more complex because there are contributions due to charge separation by charged particles, and from synchrotron radiation from e^{\pm} , both due to the Earth's magnetic field. Several experiments have also set limits on radiation due to magnetic monopoles.

32.3.2.1. The Moon as a target:

Because of it's large size and non-conducting regolith, and the availability of large radio-telescopes, the moon is an attractive target [33]; several representative lunar experiments are listed in Table 32.2. Conventional radio-telescopes are reasonably well suited to lunar neutrino searches, with natural beam widths not too dissimilar from the size of the Moon. Still, there are some experimental challenges in understanding the signal. The composition of the lunar regolith is not well known, and the attenuation length for radio waves must be estimated. An attenuation length of $9/f({\rm GHz})$ (m) is often used. The big limitation of lunar experiments is that the 240,000 km target-antenna separation leads to neutrino energy thresholds far above 10^{20} eV.

Table 32.2: Experiments that have set limits on neutrino interactions in the Moon; current limits are shown in Fig. 32.3 [32].

| Experiment | Year | Dish Size | Frequency | Bandwidth | Obs. Time |
|------------|--------|--------------------------------|-----------------------|------------------------------|-----------------------|
| Parkes | 1995 | 64 m | $1425~\mathrm{MHz}$ | $500~\mathrm{MHz}$ | 10 hrs |
| Glue | 1999 + | $70~\mathrm{m},~34~\mathrm{m}$ | $2200~\mathrm{MHz}$ | $40\text{-}150~\mathrm{MHz}$ | $120 \; \mathrm{hrs}$ |
| NuMoon | 2008 | $11{\times}25~\mathrm{m}$ | $115180~\mathrm{MHz}$ | _ | 50 hrs |
| Lunaska | 2008 | $3\times$ 22 m | $12001800~\rm{MHz}$ | _ | 6 nights |
| Resun | 2008 | $4 \times 25 \text{ m}$ | $1450~\mathrm{MHz}$ | $50~\mathrm{MHz}$ | 45 hours |

The frequency range affects the sensitive volume. At low frequencies, radiation is relatively isotropic, so signals can be detected from most of the Moon's surface, for most angles of incidence. At higher frequencies, the signal is stronger, but radiation is concentrated near the Cherenkov angle, and the geometry limits the sensitivity to interactions near the Moon's limb, where the neutrino also arrives within a fairly narrow angular range. The larger high-frequency attenuation limits the depth that can be probed.

So, higher frequency searches probe lower neutrino energies, but lower frequency searches can set tighter flux limits on high-energy neutrinos. An alternative approach, increasingly viable with modern technology, is to search over a wide frequency range. This introduces a technical challenge in the form of dispersion (frequency dependent time delays) in the ionosphere. The Parkes experiment pioneered the use of de-dispersion filters; this has been taken to a high art by the Lunaska collaboration.

Lunar experiments use several techniques to reject backgrounds, which are mostly anthropogenic. Many experiments use multiple antennas, separated by at least hundreds of meters; by requiring a coincidence within a small time window, anthropogenic noise can be rejected. An alternative approach is to use beam forming with multiple receivers in a single antenna, to ensure that the signal points back to the moon. The limits set by representative lunar experiments are shown in Fig. 32.3.

These efforts have considerable scope for expansion. In the near future, several large radio detector arrays should reach significantly lower limits. The LOFAR array is beginning to take data with 36 detector clusters spread over Northwest Europe. In the longer term, the Square Kilometer Array (SKA) with 1 km² effective area will push thresholds down to near 10^{20} eV.

${\bf 32.3.2.2.} \quad \textit{The ANITA balloon experiment:} \\$

To reduce the energy threshold, it is necessary to reduce the antenna-target separation. Most of these experiments use Antarctic ice as a medium. One such experiment is the ANITA balloon experiment which made two flights around Antarctica, floating at an altitude around 35 km [34]. Its 40 (32 in the first flight) dual-polarization horn antennas scanned the surrounding ice, out to the horizon (650 km away). Because of the small angle of incidence, ANITA was able to make use of polarization information; ν signals should be vertically polarized, while most background from cosmicray air showers is expected to be horizontally polarized. By using the several-meter separation between antennas, ANITA achieved a pointing accuracy of 0.2-0.40 in elevation, and 0.5-1.10 in azimuth.

Antarctic experiments must consider the inhomogeneities in the ice: varying density in the upper ice (the firn) and the variation in radio attenuation length with temperature. ANITA also had to consider the surface roughness, which affects the transition from ice to air. All of these affect the propagation of radio-waves from the ν -induced shower to the antennas.

The 'firn' is the top 100-200 m of Antarctic ice, where there is a transition from packed snow at the surface to solid ice (density 0.92 g/cm^3) below, where the density increases gradually with depth. The index of refraction depends on the density, so radio waves bend downward in the firn. This bending reduces the effectiveness of surface or aerial antennas. The thickness of the firn varies with location; it is thicker in central Antarctica than in the coastal ice sheets.

The attenuation length of radio waves depends on the frequency and ice temperature, with attenuation higher in warmer ice. A recent measurement, by the ARA collaboration at the South Pole found an average attenuation length of 670^{+180}_{-66} m [35]. On the Ross Ice Shelf, ARIANNA finds attenuation lengths of 300-500 m, depending on frequency [36].

ANITA verified the accuracy of their calibrations by observing radio sources that they buried in the ice. ANITA has also recently observed radio waves from cosmic-ray air showers; these showers are differentiated from neutrino showers on the basis of the radio polarization and zenith angle distribution [37].

As with the lunar experiments, ANITA had to contend with anthropogenic backgrounds. They used their good pointing accuracy to remove all candidate events that pointed toward known or suspected areas of human habitation. The limit from their two flights is shown in Fig. 32.3. These are the most stringent limits on GZK neutrinos to date. Because of the significant target to detector separation, ANITA is most sensitive at energies above 10¹⁹ eV, above the peak of the GZK neutrino spectrum.

32.3.2.3. Active Volume Detectors:

The use of radio antennas located in the active volume was pioneered by the RICE experiment, which buried radio antennas in holes drilled for AMANDA [38] at the South Pole. RICE was comprised of 18 half-wave dipole antennas, sensitive from 200 MHz to 1 GHz, buried between 100 and 300 m deep. Each antenna fed an in-situ preamplifier which transmitted the signals to surface digitizing electronics. The array triggered when four or more stations fired discriminators within 1.2 μ s, giving it a threshold of about 10^{17} eV.

Two groups are prototyping detectors, with the goal of a detector with an active volume in the $100~\rm km^3$ range. Both techniques are modular, so the detector volume scales roughly linearly with the available funding. The Askaryan Radio Array (ARA) is located at the South Pole, while the Antarctic Ross Iceshelf ANtenna Neutrino Array (ARIANNA) is on the Ross Ice Shelf. Both experiments use local triggers based on a coincidence between multiple antennas in a single station/cluster.

One big difference between the two experiments is the depth of their antennas. ARA buries antennas up to 200 m deep in the ice, to avoid the firn. Because of the refraction, a surface antenna cannot 'see' a signal from a near-surface interaction some distance away. Burying antennas avoids this problem. However, drilling holes has costs, and the limited hole diameter (15 cm in ARA) requires compromises between antenna design (particularly for horizontally polarized waves), mechanical support, power and communications. In contrast, ARIANNA places antennas in shallow, near-surface holes. This greatly simplifies deployment and avoid limitations on antenna design, but at a cost of reduced sensitivity to neutrino interactions near the surface.

The current ARA proposal, ARA-37 [35], calls for an array of 37 stations, each consisting of 16 embedded antennas deployed up to 200 m deep below the firn) in several 15-cm diameter boreholes. ARA will detect signals in the frequency range from 150 to 850 MHz for vertical polarization, and 250 MHz to 850 MHz for horizontal polarization. ARA plans to use bicone antennas for vertical polarization, and quad-slotted cylinders for horizontal polarization. The collaboration uses notch filters and surface veto antennas to eliminate most anthropogenic noise, and vetos events when aircraft are in the area, or weather balloons are being launched.

ARIANNA will be located in Moore's Bay, on the Ross Ice Shelf, where $\approx 575\,\mathrm{m}$ of ice sits atop the Ross Sea [36]. The site was chosen because the ice-seawater interface is smooth there, so the interface acts as a mirror for radio waves. The major advantage of this approach is that ARIANNA is sensitive to downward going neutrinos, and should be able to see more of the Cherenkov cone for horizontal neutrinos. One disadvantage of the site is that the ice is warmer, so the radio attenuation length will be shorter. Each ARIANNA station will use 8 log-periodic dipole antennas, pointing downward and arranged in an octagon. The multiple antennas allow for single-station directional and polarization measurements. The ARIANNA site is about 110 km from McMurdo station, and is shielded by Minna Bluff.

32.4. Large time-projection chambers for rare event detection

Written August 2009 by M. Heffner (LLNL).

The Time Projection Chamber (TPC) concept (Sec. 31.6.5) has been applied to many projects outside of particle physics and the accelerator-based experiments for which it was initially developed. TPCs in non-accelerator particle physics experiments are principally focused on rare event detection (e.g., neutrino and dark matter experiments) and the physics of these experiments can place dramatically different constraints on the TPC design (only extensions of the traditional TPCs are discussed here). The drift gas or liquid is usually the target or matter under observation and due to very low signal rates a TPC with the largest possible active mass is desired. The large mass complicates particle tracking of short and sometimes very low-energy particles. Other special design issues include efficient light collection, background rejection, internal triggering, and optimal energy resolution.

Backgrounds from γ rays and neutrons are significant design issues in the construction of these TPCs. These are generally placed

deep underground to shield them from cosmogenic particles and are surrounded with shielding to reduce radiation from the local surroundings. The construction materials are carefully screened for radiopurity, as they are in close contact with the active mass and can be a significant source of background. The TPC excels in reducing this internal background because the mass inside the field cage forms one monolithic volume from which fiducial cuts can be made ex post facto to isolate quiet drift mass. The liquid (gas) can be circulated and purified to a very high level. Self-shielding in these large mass systems can be significant and the effect improves with density and size. (See Sec. 32.6.)

The liquid-phase TPC can have a high density at low pressure that results in very good self-shielding and compact installation with lightweight containment. The down sides are the need for cryogenics, slower charge drift, tracks shorter than typical electron diffusion distances, lower-energy resolution (e.g., xenon) and limited charge readout options. Slower charge drift requires long electron lifetimes, placing strict limits on the oxygen and other impurities with high electron affinity. A significant variation of the liquid-phase TPC that improves the charge readout is the dual-phase TPC, where a gas phase layer is formed above the liquid into which the drifting electrons are extracted and amplified, typically with electroluminescence (i.e., secondary scintillation or proportional scintillation (Fig. 32.4)). The successful transfer of electrons across the phase boundary requires careful control of its position and setting up an appropriate electric field.

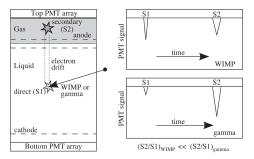

Figure 32.4: The configuration of a dual phase detector is shown on the left with the locations of where the primary and secondary light are generated. On the right is a schematic view of the signals of both an electron and nuclear interaction illustrating the discrimination power of this method. This figure is slightly modified from Ref. 39.

A high-pressure gas phase TPC has no cryogenics and density is easily optimized for the signal, but a large heavy-pressure vessel is required. Although self shielding is reduced, it can in some cases approach that of the liquid phase; in xenon at 50 atm the density is about half that of water or about 1/6 of liquid xenon. A significant feature of high pressure xenon gas is the energy resolution. Below a density of about $0.5\,\mathrm{g\,cm^{-3}}$ the intrinsic resolution is only a few times that of high purity germanium [40]. A neutrinoless double beta decay $(0\nu2\beta)$ search with a TPC operated below this density limit could enjoy excellent energy resolution and maintain particle tracking for background rejection.

An observable interaction with the TPC results in a charged particle that travels in the drift matter, exciting and ionizing the atoms until the initial energy is converted into ionization, scintillation, or heat with relatively large fluctuations around the mean. Rare-event TPCs can be designed to detect scintillation light as well as charge to exploit the anti-correlation to improve energy resolution and/or signal to noise [41]. An electric drift field separates the electrons and positive ions from the ionization although the separation is not complete and some electrons are captured, exciting atoms and releasing more light than the primary excitation alone. The average partition between the scintillation and ionization can be manipulated to increase the ionization (at the expense of scintillation) by a number of methods, such as increasing the strength of the electric field up to saturation of the ionization yield, increasing the temperature to enhance the diffusion of the ionized electrons, and adding dopants

such as triethylamine that can be photoionized by the scintillation photons releasing more ionization.

Scintillation light is typically collected with photomultiplier tubes (PMTs) and avalanche photo diodes (APDs) although any fast (compared to the ionization drift speed) light collector capable of detecting the typically UV photons, maintaining high radiopurity, and perhaps withstanding pressure would work. (CCDs are slow and therefore only record two dimensions, integrating over the time direction. Some of the 3D information can be recovered by a few PMTs.) In most cases, coating the optics or adding a wavelength shifter is required [41], although some work has been done to directly readout the 175 nm light from xenon with a silicon detector. In a typical cylindrical geometry, the light detectors are placed at the ends on an equipotential of the field cage simplifying the design, but limiting the collection efficiency. The field cage can be made of UV-reflective materials such as Teflon, to increase the light-collection efficiency.

Charge collection can be accomplished with proportional avalanche in the manner used in a traditional TPC (even in the liquid state), although the final signal suffers from rather large fluctuations caused by small fluctuations early in the avalanche that are amplified by the process. Inductive readout of passing charges and direct collection of the unamplified charge do not rely on an avalanche, and are effective where energy resolution is of paramount importance, but depend on low-noise amplifiers and relatively large signals (e.q., in $0\nu2\beta$ decay).

Electroluminescence can be used to proportionally amplify the the drifted ionization, and it does not suffer the fluctuations of an avalanche or the small signals of direct collection. It works by setting up at the positive end of the drift volume parallel meshes or wire arrays with an electric field larger than the drift field, but less than the field needed for avalanche. In xenon, this is $3-6~{\rm kV\,cm^{-1}\,bar^{-1}}$ for good energy resolution. Eq. (32.4) shows the dependence of the yield (Y) in zenon in units of photons/(electron cm bar) as a function of pressure (p) in units of bar and electric field (E) in units of ${\rm kV/cm}$ [42]:

$$Y/p = 140 E/p - 116 . (32.4)$$

The amplification can be adjusted with the length of the electroluminescence region, pressure and electric field.

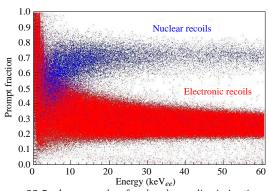

Figure 32.5: An example of pulse-shape discrimination of nuclear recoils and electrons in argon. The prompt fraction is a measure of the pulse shape that clearly separates the two interactions down to very low energy. Figure from Ref. 43.

Differentiation of nuclear and electron recoils at low-energy deposition is important as a means of background rejection. The nuclear recoil deposits a higher density of ionization than an electron recoil and this results in a higher geminate recombination resulting in a higher output of primary scintillation and lower charge. The ratio of scintillation to charge can be used to distinguish the two. In the case of an electroluminescence readout, this is done simply with the ratio of primary light to secondary light. Optically transparent grids with PMT or APD readout combine to make a elegant setup wherein the same array can measure the primary scintillation (S1), and the electroluminescence (S2) eliminating the necessity of two sets of readout detectors. Fig. 32.4 illustrates this method that works in

the gas phase and in dual phase detectors. The time evolution of the primary light is also affected by the type of recoil that results from different populations of excimers in the singlet and triplet states [43]. This alone has resulted in excellent discrimination, particularly in gasses where the decay times are significantly different (see Table 32.3). An example of the discrimination is displayed in Fig. 32.5, where nuclear recoils and electrons can be identified down to 10's of keV $_{ee}$, in argon. Nuclear recoils deposit less ionization than electrons at a given energy. For this reason, nuclear recoil energy is typically reported in equivalent electron energy loss, keV $_{ee}$, when compared with electrons.

The composition of the drift matter is an important choice in TPC design, and the noble gasses are frequently selected as the bulk element in the mix (Table 32.3). The noble gases have no electron affinity in the ground state, resulting in good free-electron lifetime and a good amount of scintillation that is useful for particle identification and t_0 determination. In the case of argon and xenon, the low average energy to produce an ion pair results in good energy resolution. The noble gases are easily purified to a high level that, combined with moderate cost, enables the construction of large monolithic detectors. Of the noble gases one isotope of xenon (136 Xe) is a candidate for ($^{0}\nu2\beta$).

Table 32.3: Properties of the noble gasses typically used in non-accelerator TPCs [44,45]. W is the average energy spent to produce one electron ion pair.

| Element | W (eV) | | length | decay time (fast/slow) | cost* (\$/kg) |

The negative-ion TPC [46] uses an electronegative gas $(e.g., \text{CS}_2)$ either as the drift gas or as a dopant to the drift gas that captures the primary electrons, forming negative ions that drift in the electric field. Upon reaching the gas-gain region of the TPC, the electron is stripped from the ion in the high electric field, and the electron avalanches in the normal manner. The larger mass of the the negative ion keeps the kinetic energy of the ion thermal at high electric fields, and therefore such a TPC exhibits far less diffusion. The reduction of diffusion over large distance (time) enables detailed tracking of small tracks in a large volume without the benefit of a magnetic field to limit diffusion (which would be prohibitively expensive for a large volume). The trade-off is orders-of-magnitude slower drift, placing a limit on the trigger rate.

32.5. Sub-Kelvin detectors

Written September 2009 by S. Golwala (Caltech).

Detectors operating below 1 K, also known as "low-temperature" or "cryogenic" detectors, use ≲meV quanta (phonons, superconducting quasiparticles) to provide better energy resolution than is typically available from conventional technologies. Such resolution can provide unique advantages to applications reliant on energy resolution, such as beta-decay experiments seeking to measure the ν_e mass or searches for neutrinoless double-beta decay. In addition, the sub-Kelvin mode is combined with conventional (eV quanta) ionization or scintillation measurements to provide discrimination of nuclear recoils from electron recoils, critical for searches for WIMP dark matter and for coherent neutrino-nucleus scattering. We describe the techniques in generic fashion in the text and provide a list of experiments using these techniques in An excellent review [47] is available that covers this material and other applications of low-temperature detectors. The proceedings of the Low Temperature Detectors Workshops are also useful [48].

32.5.1. Thermal Phonons:

The most basic kind of low-temperature detector employs a dielectric absorber coupled to a thermal bath via a weak link. A thermistor monitors the temperature of the absorber. The energy E deposited by a particle interaction causes a calorimetric temperature change by increasing the population of thermal phonons. The fundamental sensitivity is

$$\sigma_E^2 = \xi^2 kT [T C(T) + \beta E] ,$$
 (32.5)

where C is the heat capacity of the detector, T is the temperature of operation, k is Boltzmann's constant, and ξ is a dimensionless factor of order unity that is precisely calculable from the nature of the thermal link and the non-thermodynamic noises (e.g., Johnson and/or readout noise). The first term is imposed by statistical fluctuations in the number of thermally excited phonons and on the energy in the absorber due to exchange with the thermal bath (see, e.g., Ref. 49 and references therein). The second term is due to statistical fluctuations in the number of phonons excited by the absorbed radiation. The factor β is also dimensionless and $\mathcal{O}(1)$ and is also precisely calculable from the nature of the thermal link. The ratio of the second term to the first term is equal to the fractional absorber temperature change due to an energy deposition. Thus, the second term becomes appreciable when this fractional temperature change is appreciable. at which point nonlinear effects also come into play. The energy resolution typically acquires an additional energy dependence due to deviations from an ideal calorimetric model that cause position and/or energy dependence in the signal shape.

The rise time of response is limited by the internal thermal conductivity of the absorber. The decay time constant, describing the time required for the absorbed energy to flow out to the bath, is $\tau = C/G$, where G is the thermal conductance of the weak link. The above formula immediately suggests the use of crystalline dielectric absorbers and low temperatures because of the linear factor of T and because T for crystalline dielectrics drops as T^3 for T well below the material's Debye temperature (Θ_D , typically hundreds of K). Specifically, the Debye model indicates that a crystal consisting of T atoms has

$$C = \frac{12\pi^4}{5} N k \left(\frac{T}{\Theta_D}\right)^3 \tag{32.6}$$

which gives $\sigma_E = 5.2 \, \xi$ eV for 1 kg of germanium operated at T=10 mK. (For a detector of this size the 2nd term in Eq. (32.5) is negligible.) In practice, a number of factors degrade the above result by about an order of magnitude (thermistor heat capacity and power dissipation, readout noise, etc.), but the predicted energy resolution for such a large mass remains attractive.

Neutron-transmutation-doped (NTD) germanium and implanted silicon semiconductors are used for thermistors. Conduction is via phonon-assisted hopping between impurity sites, vielding an exponentially decreasing resistance as a function of temperature, R(T), with negative slope, dR/dT. Attachment to the absorber is usually by eutectic bonding or epoxy or by direct implantation into the absorber. Another type of temperature sensor is the superconducting phase-transition thermometers (SPT) or transition-edge sensor (TES). A SPT or TES is a superconducting film operated in the transition from superconductive to normal resistance at the transition temperature, T_c , where its resistance is a strong function of temperature with positive dR/dT. This can provide strong electrothermal negative feedback, which improves linearity, speeds up response, and mitigates variations in T_c among multiple TESs on the same absorber. Nb_xSi_{1-x} is another thermistor material that ranges between the semiconducting and superconducting regimes as a function of the stoichiometry (defined by x). SPTs/TESs and Nb $_x$ Si $_{1-x}$ thermistors are frequently deposited directly onto the absorber by sputtering or evaporation.

The readout method depends on the type of thermometer used. Doped semiconductors typically have high impedances and are well matched to low-noise JFET-based readout while SPTs/TESs are low-impedance devices requiring SQUID amplifiers.

Table 32.4: Selected experiments using sub-Kelvin detectors. The table is not exhaustive. Operation mode, detector and excitation sensor construction, baseline energy resolution, and energy resolution at a particular energy of interest E_0 are given. We quote the energy and energy resolution for "total" phonon signal, where the total phonon signal includes both recoil energy and, where relevant, drift heating. Ionization and scintillation energies are normalized so that, for electron recoils, the energy in these channels is equal to the recoil energy ("electronequivalent" energies). For scintillation energy, this is the electron-equivalent energy deposited in the target detector, not the energy received by the photon absorber. Approximate dates of operation are also given. Key to comments: "a-Si" and "a-Ge" = amorphous silicon or germanium layers in ionization electrodes. "H-a-Si" = hydrogenated amorphous silicon. "P-implanted" = phosphorous implantation. "Interdig." = interdigitated ionization electrode design that provides some z information from ionization signal asymmetry. "Surface-event discrimination" = ability to reject events near surfaces that suffer reduced ionization yield and can be misidentified as WIMPs. "w/phonons" = using athermal phonon pulse rising edge (faster for surface events). "w/ioniz. asym." = using the asymmetry of the ionization signal on electrodes on opposite faces of interdigitated-electrode detectors. "w/phonon asym." = using the asymmetry of the phonon signal detected on opposite detector faces. "U" = not known by author. SuperCDMS energy resolutions have not been fully reported yet but are likely no worse than CDMS II.

32.5.2. Athermal Phonons and Superconducting Quasiparticles:

The advantage of thermal phonons is also a disadvantage: energy resolution degrades as \sqrt{M} where M is the detector mass. This motivates the use of athermal phonons. There are three steps in the development of the phonon signal. The recoiling particle deposits energy along its track, with the majority going directly into phonons. (A minority of the energy goes directly into scintillation and ionization. Energy deposited in ionization is recovered when the carriers recombine.) The recoil and bandgap energy scales (keV and higher, and eV, respectively) are much larger than phonon energies (meV), so the full energy spectrum of phonons is populated, with phase space favoring the most energetic phonons. However, these initial energetic phonons do not propagate because of isotopic scattering (scattering due to variations in lattice ion atomic mass, rate $\propto \nu^4$ where ν is the phonon frequency) and anharmonic decay (scattering wherein a single phonon splits into two phonons, rate $\propto \nu^5$). Anharmonic decay downshifts the phonon spectrum, which increases the phonon mean free path, so that eventually phonons can propagate the characteristic dimension of the detector. These phonons travel quasiballistically, preserve information about the position of the parent interaction, and are not affected by an increase in detector mass (modulo the concomitant larger distance to the surface where they can be sensed). Anharmonic decay continues until a thermal distribution is reached (µeV at mK temperatures), which is exhibited as a thermal increase in the temperature of the detector. If one can detect the athermal phonons at the crystal surface, keep the density of such sensors fixed as the detector surface area increases with mass, and the crystals are pure enough that the athermal phonons can propagate to the surface prior to thermalization, then an increase in detector mass need not degrade energy resolution, and can in fact improve position reconstruction. Sensors for athermal phonons are similar to those for superconducting quasiparticles described below.

Another mode is detection of superconducting quasiparticles in superconducting crystals. Energy absorption breaks superconducting Cooper pairs and yields quasiparticles, electron-like excitations that can diffuse through the material and that recombine after the quasiparticle lifetime. In crystals with very large mean free path against scattering, the diffusion length (distance traveled in a quasiparticle lifetime) is large enough (mm to cm) that the quasiparticles reach the surface and can be detected, usually in a superconducting tunnel junction (STJ) or TES/SPT.

A similar technique is applied to detect athermal phonons. Athermal phonons reaching a superconducting film on the detector surface generate quasiparticles as above. Such thin films have diffusion lengths much shorter than for superconducting crystalline substrates, only of order 100 $\mu \rm m$ to 1 mm. Thus, the superconducting film must be segmented on this length scale and have a quasiparticle sensor for each segment. The sensors may, however, be connected in series or parallel in large groups to reduce readout channel count.

The readout for athermal phonon and quasiparticle sensing depends on the type of quasiparticle detector. Tunnel junctions match well to JFET-based readouts, while TESs/SPTs use SQUID amplifiers.

32.5.3. Ionization and Scintillation:

While ionization and scintillation detectors usually operate at much higher temperatures, ionization and scintillation can be measured at low temperature and can be combined with a "sub-Kelvin" technique to discriminate nuclear recoils from background interactions producing electron recoils, which is critical for WIMP searches and coherent neutrino-nucleus scattering. With ionization, such techniques are based on Lindhard theory [50], which predicts substantially reduced ionization yield for nuclear recoils relative to electron recoils. For scintillation, application of Birks' law (Sec. 31.3.0) yields a similar prediction. (The reduced ionization or scintillation yield for nuclear recoils is frequently referred to as "quenching".)

Specifically, consider the example of measuring thermal phonons and ionization. All the deposited energy eventually appears in the thermal phonon channel, regardless of recoil type (modulo some loss to permanent crystal defect creation). Thus, the ionization yield—the number of charge pairs detected per unit detected energy in phonons—provides a means to discriminate nuclear recoils from

electron recoils. Similar discrimination is observed with athermal phonons and ionization and with phonons and scintillation.

In semiconducting materials of sufficient purity—germanium and silicon—electron-hole pairs created by recoiling particles can be drifted to surface electrodes by applying an electric field, similar to how this is done at 77 K in high-purity germanium photon spectrometers (Sec. 31.7). There are three important differences, however, that result in the use of low fields—of order 1 V/cm—instead of the hundreds to thousands of V/cm used in 77 K detectors. First, high fields are required at 77K to deplete the active volume of thermally excited mobile carriers. At low temperature and in crystals of purity high enough to drift ionization with negligible trapping, the population of thermally excited carriers is exponentially suppressed due to the low ambient thermal energy. Second, high fields in 77K operation prevent trapping of drifting carriers on ionized impurities and crystalline defects and/or overcome space charge effects. At low temperatures, ionized impurities and space charge can be neutralized (using free charge created by photons from LEDs or radioactive sources) and remain in this state for minutes to hours. This reduces trapping exponentially and allows low-field drift. Third, a high field in a sub-Kelvin detector would result in a massive phonon signal from the drifting carriers, fully correlated with the ionization signal and thereby eliminating nuclear recoil discrimination. Readout of the charge signal is typically done with a conventional JFET-based transimpedance amplifier.

A number of materials that scintillate on their own (i.e., without doping) continue to do so at low temperatures, including BaF₂, BGO, CaWO₄, ZnWO₄, PbWO₄, and other tungstates and molybdates. In and of itself, there is little advantage to a low-temperature scintillation measurement because detecting the scintillation is nontrivial, the quanta are large, and the detection efficiency is usually poor. Such techniques are pursued only in order to obtain nuclear-recoil discrimination. Conventional photodetectors do not operate at such low temperatures, so one typically detects the scintillation photons in an adjacent low-temperature detector that is thermally disconnected from but resides in an optically reflective cavity with the target detector.

32.6. Low-radioactivity background techniques

Written August 2009 by A. Piepke (University of Alabama).

The physics reach of low-energy rare event searches e.g. for dark matter, neutrino oscillations, or double beta decay is often limited by background caused by radioactivity. Depending on the chosen detector design, the separation of the physics signal from this unwanted interference can be achieved on an event-by-event basis by active event tagging, utilizing some unique event feature, or by reducing the radiation background by appropriate shielding and material selection. In both cases, the background rate is proportional to the flux of background-creating radiation. Its reduction is thus essential for realizing the full physics potential of the experiment. In this context, "low energy" may be defined as the regime of natural, anthropogenic, or cosmogenic radioactivity, all at energies up to about 10 MeV. Following the classification of [51], sources of background may be categorized into the following classes:

- 1. environmental radioactivity,
- 2. radioimpurities in detector or shielding components,
- 3. radon and its progeny,
- 4. cosmic rays,
- 5. neutrons from natural fission, (α, n) reactions and from cosmic-ray muon spallation and capture.

32.6.1. Defining the problem: The application defines the requirements. Background goals can be as demanding as a few low-energy events per year in a ton-size detector. The strength of the physics signal to be measured can often be estimated theoretically or from limits derived by earlier experiments. The experiments are then designed for the desired signal-to-background ratio. This requires finding the right balance between clarity of measurement, ease of construction, and budget. In a practical sense, it is important to formulate background goals that are sufficient for the task at hand but doable, in a finite time. It is now standard practice to use a detector simulation to translate the background requirements into

limits for the radioactivity content of various detector components, requirements for the radiation shielding, and allowable cosmic-ray flux. This strategy allows identifing the most critical components early and the allocation of analysis and development resources accordingly. The CERN code GEANT4 is a widely used tool for this task. It contains sufficient nuclear physics to allow accurate background estimations. Custom-written event generators, modeling particle correlations in complex decay schemes, are used as well.

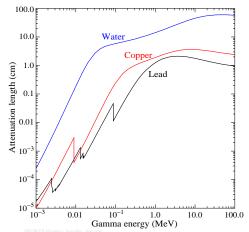

Figure 32.6: γ-ray attenuation lengths in some common shielding materials. The mass attenuation data has been taken from the NIST data base XCOM; see "Atomic Nuclear Properties" at pdg.lbl.gov.

32.6.2. Environmental radioactivity: The long-lived natural radioisotopes 40 K, 232 Th, and 238 U have average abundances of 2.4, 9.6 and 2.7 ppm in the earth's crust, with large local variations. In most applications, γ radiation emitted by natural radioactivity constitutes the dominant contribution to the local radiation field. Typical low-background applications require levels of natural radioactivity on the order of ppb or ppt in the detector components. Passive or active shielding is used to suppress external γ radiation down to that level. Fig. 32.6 shows the energy-dependent attenuation length $\lambda(E_{\gamma})$ as a function of γ ray energy E_{γ} for three common shielding materials (water, copper, lead). The thickness ℓ required to reduce the external flux by a factor f>1 is estimated assuming exponential damping:

$$\ell = \lambda(E_{\gamma}) \cdot \ln f . \tag{32.7}$$

At 100 keV, a typical energy scale for dark matter searches (or 2.615 MeV, for a typical double-beta decay experiment), attenuation by a factor $f=10^5$ requires 67(269) cm of H₂O, 2.8(34) cm of Cu, or 0.18(23) cm of Pb. Such estimates allows for an order-of-magnitude estimate of the experiment dimensions. A precise estimation of the leakage of external γ radiation, including scattering and the effect of energy cuts, requires Monte Carlo simulations and determination of the radioactivity present in the laboratory. Detailed modeling of the γ flux in a large laboratory, or inside hermetic shielding, needs to cope with very small detector-hit efficiencies. It is often advantageous to calculate solid angle and mass attenuation separately. This approach reduces the computation time required for a statistically meaningful number of detector hits to manageable levels.

Because of its low density, water has relatively long attenuation lengths, resulting in rather voluminous shields. However, because water can be obtained relatively cheaply in large amounts, it has become the medium of choice for most large detectors. Water purification technology is effective and commercially available, an important consideration in view of the intrinsic radioactivity of the shield, to be discussed below. High-purity water, instrumented with photo multiplier tubes, can further serve as a Cherenkov cosmic-ray veto detector. Liquefied gases are being used for shielding as well.

32.6.3. Radioimpurities in detector or shielding components

: After suppressing the effect of external radioactivity, radioactive impurities contained in the detector components or attached to its surfaces become important. Any material is radioactive at some level. The activity can be natural, cosmogenic, or man-made. The determination of the activity content of a specific material or component requires case-by-case analysis, and is almost never obtainable from the manufacturer. However, there are some general rules than can be used to guide the pre-selection. For detectors designed to look for electrons (for example in double-beta decay searches or neutrino detection via inverse beta decay or elastic scattering), this is the principal source of background. For devices detecting nuclear recoils (for example in dark matter searches), this is often of secondary importance as ionization signals can be actively suppressed on an event-by-event basis.

For natural radioactivity, a rule of thumb is that synthetic substances are cleaner than natural materials. Typically, more highly processed materials have lower activity content. Substances with smaller chemical reactivity tend to be cleaner. The refining process tends to remove K, Th, and U. For example, Al is often found to contain considerable amounts of Th and U, while electrolytic Cu is very low in primordial activities. Plastics or liquid hydrocarbons, having been refined by distillation, are often quite radiopure. Tabulated radioactivity screening results for a wide range of materials can be found in Refs. 52 and 53.

The long-lived $^{238}\mathrm{U}$ daughter $^{210}\mathrm{Pb}$ $(T_{1/2}{=}22.3~\mathrm{y})$ is found in all shielding lead, and is a background concern at low energies. This is due to the relatively high endpoint energy $(\mathrm{Q}_{\beta}{=}1.162~\mathrm{MeV})$ of its beta-unstable daughter $^{210}\mathrm{Bi}$. Lead parts made from selected low-U ores have specific activities of about 5–30 mBq/kg. For lower activity, ancient lead (for example from Roman ships) has been used. Because the ore processing and lead refining removed most of the $^{238}\mathrm{U}$, the $^{210}\mathrm{Pb}$ decayed during the long waiting time to the level supported by the U-content of the refined lead. Lining the lead with copper to range out the low-energy radiation is another remedy. However, intermediate Z materials are an activation risk when handled above ground, as will be discussed below. $^{210}\mathrm{Pb}$ is also found in solders.

The fission product $^{137}\mathrm{Cs}$ can be found attached to the surface of materials. The radioactive noble gas $^{85}\mathrm{Kr}$, released into the atmosphere by nuclear reactors and nuclear fuel re-processing, is also important, especially due to its high solubility in organic materials. Post-World War II steel typically contains a few tens of mBq/kg of $^{60}\mathrm{Co}$.

Surface activity is not a material property but is added during manufacturing and handling. It can often be effectively removed by etching. Installation of low-background detectors is often done in clean rooms to avoid this contamination. Surface contamination can be quantified by means of wipe-testing with acid or alcohol wetted Whatman 41 filters. The paper filters are ashed after wiping and the residue is digested in acid. Subsequent analysis by means of mass spectroscopy or neutron activation analysis is capable of detecting less than 1 pg/cm² of Th and U. The most demanding low-rate experiments require screening of all components, which can be a time consuming task. The requirements for activity characterization depend on the experiment and the location and amount of a particular component. Monte Carlo simulations are used to quantify these requirements. Activities of the order $\mu Bq/kg$ or even below may need to be detected in the process. At such level of sensitivity, the characterization becomes a challenging problem in itself. Low-background α , β , and γ ray counting, mass spectroscopy, and neutron activation analysis are used.

32.6.4. Radon and its progeny: The noble gas $^{222}\mathrm{Rn}$, a pure $\alpha\text{-emitter}$, is a $^{238}\mathrm{U}$ decay product. Due to its half-life of 3.8 d it is released by surface soil and is found in the atmosphere everywhere. $^{220}\mathrm{Rn}$ ($^{232}\mathrm{Th}$ decay product) is unimportant because of its short half-life. $^{222}\mathrm{Rn}$ activity in air ranges from 10 to 100 mBq/L outdoors and 100 to thousands of mBq/L indoors. The natural radon concentration depends on the weather and shows daily and seasonal variations. Radon levels are lowest above the oceans. For electron detectors, it is not the Rn itself that creates background, but its progeny $^{214}\mathrm{Pb},$ $^{210}\mathrm{Bi},$ which emit energetic beta and γ radiation. Thus, not

only the detector itself has to be separated from contact with air, but also internal voids in the shield which contain air can be a background concern. Radon is quite soluble in water and even more so in organic solvents. For large liquid scintillation detectors, radon mobility due to convection and diffusion is a concern. To define a scale: typical double-beta-decay searches are disturbed by a μ Bq (or 1/11.6 d) activity of 222 Rn contained in the detector medium. This corresponds to a steady-state population of 0.5 atoms in 50 μ L of air (assuming 20 mBq/L of radon in the air). The criteria for leak tightness are thus quite demanding. The decay of Rn itself is a concern for some recoil type detectors, as nuclear recoil energies in α decays are substantial (76 keV in case of 222 Rn).

Low-activity detectors are often kept sealed from the air and continuously flushed with boil-off nitrogen, which contains only small amounts of Rn. For the most demanding applications, the nitrogen is purified by multiple distillations. Then only the Rn outgassing of the piping (due to its U internal content) determines the radon concentration. Radon diffuses readily through thin plastic barriers. If the detector is to be isolated from its environment by means of a membrane, the right choice of material is important [54].

If energies below 1 MeV are to be measured, additional care has to be taken to avoid plate-out of the long-lived radon daughter ²¹⁰Pb on the surfaces. This can be reduced by keeping the parts under a protective low-radon cover gas.

Radon can be detected even at the level of few atoms with solid state, scintillation, or gas detectors by exploiting the fast decay sequences of $^{214}\mathrm{Bi}$ and $^{214}\mathrm{Po}$. The efficiency of these devices is sometimes boosted by electrostatic collection of charged radon into a small detector.

32.6.5. Cosmic rays: Cosmic radiation, discussed in detail in Chapter 26, is a source of background for just about any non-accelerator experiment. Primary cosmic rays are about 90% protons, 9% alpha particles, and the rest heavier nuclei (Fig. 26.1). They are totally attenuated within the first the first few hg/cm² of atmospheric thickness. At sea level secondary particles $(\pi^{\pm}:p:e^{\pm}:n:\mu^{\pm})$ are observed with relative intensities (1:13:340:480:1420) for E<1 GeV (Ref. 55; also see Fig. 26.3).

All but the muon and the neutron components are readily absorbed by overburden such as building ceilings and passive shielding. Only if there is very little overburden (less than a few \times 10 g cm⁻² in rock) do pions and protons need to be considered when estimating the production rate of cosmogenic radioactivity.

Sensitive experiments are thus operated deep underground where essentially only muons penetrate. As shown in Fig. 26.6, the muon intensity falls off rapidly with depth. Active detection systems capable of tagging events correlated in time with cosmic-ray activity are needed, depending on the overburden. Such experiments are described in Sec. 32.3.1.

The muonic background is only related to low-radioactivity techniques insofar as photonuclear interactions of muons can produce long-lived radioactivity. This happens at any depth, and it constitutes an essentially irreducible background.

Cosmogenic activation of components brought from the surface is also an issue. Proper management of parts and materials above ground during machining and detector assembly minimizes the accumulation of long-lived activity. Cosmogenic activation is most important for intermediate Z materials such as Cu and Fe. For the most demanding applications, metals are stored and transported under sufficient shielding to stop the hadronic component of the cosmic rays. Parts, e.g., the nickel tubes for the ³He counters in SNO, can be stored underground for long periods before being used. Underground machine shops are also sometimes used to limit the duration of exposure at the surface.

32.6.6. Neutrons: Neutrons contribute to the background of low-energy experiments in different ways: directly through nuclear recoil in the detector medium, and indirectly, through the production of radio nuclides inside the detector and its components. The latter mechanism allows even remote materials to contribute to the background by means of penetrating γ radiation, since inelastic scattering of fast neutrons or radiative capture of slow neutrons can result in the emission of γ radiation. Neutrons are thus an important source of

low-energy background. They are produced in different ways:

- At the earth's surface neutrons are the most frequent cosmic-ray secondaries other than muons;
- Energetic tertiary neutrons are produced by cosmic-ray muons in nuclear spallation reactions with the detector and laboratory walls;
- In high Z materials, often used in radiation shields, nuclear capture of negative muons results in emission of neutrons;
- 4. Natural radioactivity has a neutron component through spontaneous fission and $(\alpha,n)\text{-reactions}.$

A calculation with the hadronic simulation code FLUKA, using the known energy distribution of secondary neutrons at the earth's surface [56], yields a mass attenuation of 1.5 hg/cm² in concrete for secondary neutrons. If energy-dependent neutron-capture cross sections are known, then such calculations can be used to obtain the production rate of radio nuclides.

At an overburden of only few meters, water equivalent neutron production by muons becomes the dominant mechanism. Neutron production rates are high in high-Z shielding materials. A high-Z radiation shield, discussed earlier as being effective in reducing background due to external radioactivity, thus acts as a source for cosmogenic tertiary high-energy neutrons. Depending on the overburden and the radioactivity content of the laboratory, there is an optimal shielding thickness. Water shields, although bulky, are an attractive alternative due to their low neutron production yield and self-shielding.

Neutron shields made from plastic or water are commonly used to reduce the neutron flux. The shield is sometimes doped with a substance having a high thermal neutron capture cross section (such as boron) to absorb thermal neutrons more quickly. The hydrogen serves as a target for elastic scattering, and is effective in reducing the neutron energy. Neutrons from natural radioactivity have relatively low energies and can be effectively suppressed by a neutron shield. Such a neutron shield should be inside the lead to be effective for tertiary neutrons. However, this is rarely done as it increases the neutron production target (in form of the passive shield), and costs increase as the cube of the dimensions. An active cosmic-ray veto is an effective solution, correlating a neutron with its parent muon. This solution works best if the veto system is as far removed from the detector as feasible (outside the radiation shield) to correlate as many background-producing muons with neutrons as possible. The vetoed time after a muon hit needs to be sufficiently long to assure neutron thermalization. The average thermalization and capture time in lead is about 900 μ s [51]. The veto-induced deadtime, and hence muon hit rate on the veto detector, is the limiting factor for the physical size of the veto system (besides the cost). The background caused by neutron-induced radioactivity with live times exceeding the veto time cannot be addressed in this way. Moving the detector deep underground, and thus reducing the muon flux, is the only technique addressing all sources of neutron background.

33. RADIOACTIVITY AND RADIATION PROTECTION

Revised August 2011 by S. Roesler and M. Silari (CERN).

33.1. Definitions [1,2]

33.1.1. Physical quantities:

• Fluence, Φ (unit: $1/m^2$): The fluence is the quotient of dN by da, where dN is the number of particles incident upon a small sphere of cross-sectional area da

$$\Phi = dN/da . (33.1)$$

In dosimetric calculations, fluence is frequently expressed in terms of the lengths of the particle trajectories. It can be shown that the fluence, Φ , is given by

$$\Phi = dl/dV$$

where dl is the sum of the particle trajectory lengths in the volume dV

- \bullet Absorbed dose, D (unit: gray, 1 Gy=1 J/kg=100 rad): The absorbed dose is the energy imparted by ionizing radiation in a volume element of a specified material divided by the mass of this volume element
- Kerma, K (unit: gray): Kerma is the sum of the initial kinetic energies of all charged particles liberated by indirectly ionizing radiation in a volume element of the specified material divided by the mass of this volume element.
- Linear energy transfer, L or LET (unit: J/m, often given in $\text{keV}/\mu\text{m}$): The linear energy transfer is the mean energy, dE, lost by a charged particle owing to collisions with electrons in traversing a distance dl in matter. Low-LET radiation: x rays and gamma rays (accompanied by charged particles due to interactions with the surrounding medium) or light charged particles such as electrons that produce sparse ionizing events far apart at a molecular scale $(L < 10 \text{ keV}/\mu\text{m})$. High-LET radiation: neutrons and heavy charged particles that produce ionizing events densely spaced at a molecular scale $(L > 10 \text{ keV}/\mu\text{m})$.
- Activity, A (unit: becquerel, 1 Bq=1/s=27 picocurie): Activity is the expectation value of the number of nuclear decays occurring in a given quantity of material per unit time.

${\bf 33.1.2.} \quad Protection \ quantities:$

Protection quantities are dose quantities developed for radiological protection that allow quantification of the extent of exposure of the human body to ionizing radiation from both whole and partial body external irradiation and from intakes of radionuclides.

• Organ absorbed dose, D_T (unit: gray): The mean absorbed dose in an organ or tissue T of mass m_T is defined as

$$D_T = \frac{1}{m_T} \int_{m_T} D dm \ .$$

• Equivalent dose, H_T (unit: sievert, 1 Sv=100 rem): The equivalent dose H_T in an organ or tissue T is equal to the sum of the absorbed doses $D_{T,R}$ in the organ or tissue caused by different radiation types R weighted with so-called radiation weighting factors w_R :

$$H_T = \sum_R w_R \times D_{T,R} \ . \tag{33.2}$$

It expresses long-term risks (primarily cancer and leukemia) from low-level chronic exposure. The values for w_R recommended by ICRP [2] are given in Table 33.1.

• Effective dose, E (unit: sievert): The sum of the equivalent doses, weighted by the tissue weighting factors w_T ($\sum_T w_T = 1$) of several organs and tissues T of the body that are considered to be most sensitive [2], is called "effective dose":

$$E = \sum_{T} w_T \times H_T \ . \tag{33.3}$$

Table 33.1: Radiation weighting factors, w_R .

| Radiation type | w_R |
|--------------------------------------------|-----------------------------------------------|
| Photons, electrons and muons | 1 |
| Neutrons, $E_n < 1 \text{ MeV}$ | $2.5 + 18.2 \times \exp[-(\ln E_n)^2/6]$ |
| $1 \text{ MeV} \le E_n \le 50 \text{ MeV}$ | $5.0 + 17.0 \times \exp[-(\ln(2E_n))^2/6]$ |
| $E_n > 50 \text{ MeV}$ | $2.5 + 3.25 \times \exp[-(\ln(0.04E_n))^2/6]$ |
| Protons and charged pions | 2 |
| Alpha particles, fission | |
| fragments, heavy ions | 20 |

${\bf 33.1.3.} \quad Operational \ quantities:$

The body-related protection quantities, equivalent dose and effective dose, are not measurable in practice. Therefore, operational quantities are used for the assessment of effective dose or mean equivalent doses in tissues or organs. These quantities aim to provide a conservative estimate for the value of the protection quantity.

- Ambient dose equivalent, $H^*(10)$ (unit: sievert): The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded and aligned field in a 30 cm diameter sphere of unit density tissue (ICRU sphere) at a depth of 10 mm on the radius vector opposing the direction of the aligned field. Ambient dose equivalent is the operational quantity for area monitoring.
- Personal dose equivalent, $H_p(d)$ (unit: sievert): The dose equivalent in ICRU tissue at an appropriate depth, d, below a specified point on the human body. The specified point is normally taken to be where the individual dosimeter is worn. For the assessment of effective dose, $H_p(10)$ with a depth d=10 mm is chosen, and for the assessment of the dose to the skin and to the hands and feet the personal dose equivalent, $H_p(0.07)$, with a depth d=0.07 mm, is used. Personal dose equivalent is the operational quantity for individual monitoring.

${\bf 33.1.4.} \quad Dose\ conversion\ coefficients:$

Dose conversion coefficients allow direct calculation of protection or operational quantities from particle fluence and are functions of particle type, energy and irradiation configuration. The most common coefficients are those for effective dose and ambient dose equivalent. The former are based on simulations in which the dose to organs of anthropomorphic phantoms is calculated for approximate actual conditions of exposure, such as irradiation of the front of the body (antero-posterior irradiation) or isotropic irradiation.

Conversion coefficients from fluence to effective dose are given for anterior-posterior irradiation and various particles in Fig. 33.1 [3]. For example, the effective dose from an anterior-posterior irradiation in a field of 1-MeV neutrons with a fluence of 1 neutron per $\rm cm^2$ is about 290 pSv. In Monte Carlo simulations such coefficients allow multiplication with fluence at scoring time such that effective dose to a human body at the considered location is directly obtained.

33.2. Radiation levels [4]

- Natural background radiation: On a worldwide average, the annual whole-body dose equivalent due to all sources of natural background radiation ranges from 1.0 to 13 mSv (0.1–1.3 rem) with an annual average of 2.4 mSv [5]. In certain areas values up to 50 mSv (5 rem) have been measured. A large fraction (typically more than 50%) originate from inhaled natural radioactivity, mostly radon and radon daughters. The latter can vary by more than one order of magnitude: it is 0.1–0.2 mSv in open areas, 2 mSv on average in a house and more than 20 mSv in poorly ventilated mines.
- Cosmic ray background radiation: At sea level, the whole-body dose equivalent due to cosmic ray background radiation is dominated by muons; at higher altitudes also nucleons contribute. Dose equivalent rates range from less than $0.1~\mu \text{Sv/h}$ at sea level to a few $\mu \text{Sv/h}$ at aircraft altitudes. Details on cosmic ray fluence levels are given in the Cosmic Rays section (Sec. 26 of this Review).

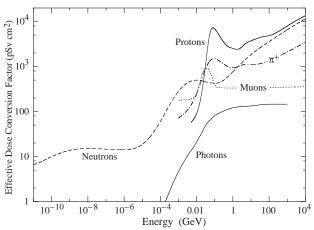

Figure 33.1: Fluence to effective dose conversion coefficients for anterior-posterior irradiation and various particles [3].

• Fluence to deposit one Gy: Charged particles: The fluence necessary to deposit a dose of one Gy (in units of cm⁻²) is about $6.24 \times 10^9/(dE/dx)$, where dE/dx (in units of MeV g⁻¹ cm²) is the mean energy loss rate that may be obtained from Figs. 30.2 and 30.4 in Sec. 30 of this Review, and from http://pdg.lbl.gov/AtomicNuclearProperties. For example, it is approximately 3.5×10^9 cm⁻² for minimum-ionizing singly-charged particles in carbon. Photons: This fluence is about $6.24 \times 10^9/(Ef/\ell)$ for photons of energy E (in MeV), an attenuation length ℓ (in g cm⁻²), and a fraction $f \lesssim 1$, expressing the fraction of the photon energy deposited in a small volume of thickness $\ll \ell$ but large enough to contain the secondary electrons. For example, it is approximately 2×10^{11} cm⁻² for 1 MeV photons on carbon ($f \approx 1/2$).

33.3. Health effects of ionizing radiation

Radiation can cause two types of health effects, deterministic and stochastic:

- ullet **Deterministic effects** are tissue reactions which cause injury to a population of cells if a given threshold of absorbed dose is exceeded. The severity of the reaction increases with dose. The quantity in use for tissue reactions is the absorbed dose, D. When particles other than photons and electrons (low-LET radiation) are involved, a Relative Biological Effectiveness (RBE)-weighted dose may be used. The RBE of a given radiation is the reciprocal of the ratio of the absorbed dose of that radiation to the absorbed dose of a reference radiation (usually x rays) required to produce the same degree of biological effect. It is a complex quantity that depends on many factors such as cell type, dose rate, fractionation, etc.
- Stochastic effects are malignant diseases and heritable effects for which the probability of an effect occurring, but not its severity, is a function of dose without threshold.
- Lethal dose: The whole-body dose from penetrating ionizing radiation resulting in 50% mortality in 30 days (assuming no medical treatment) is 2.5–4.5 Gy (250–450 rad) † , as measured internally on the body longitudinal center line. The surface dose varies due to variable body attenuation and may be a strong function of energy.
- Cancer induction: The cancer induction probability is about 5% per Sv on average for the entire population [2].
- Recommended effective dose limits: The International Commission on Radiological Protection (ICRP) recommends a limit for radiation workers of 20 mSv effective dose per year averaged over 5 years, with the provision that the dose should not exceed 50 mSv in any single year [2]. The limit in the EU-countries and Switzerland is 20 mSv per year, in the U.S. it is 50 mSv per year (5 rem per year). Many physics laboratories in the U.S. and elsewhere set lower limits. The effective dose limit for general public is typically 1 mSv per year.

33.4. Prompt neutrons at accelerators

Neutrons dominate the particle environment outside thick shielding (e.g., > 1 m of concrete) for high energy (> a few hundred MeV) electron and hadron accelerators.

33.4.1. Electron accelerators:

At electron accelerators, neutrons are generated via photonuclear reactions from bremsstrahlung photons. In the photon energy range from threshold (few MeV) to about 30 MeV, neutron production is via the Giant Dipole Resonance (GDR) mechanism. The reaction consists in a collective excitation of the nucleus, in which neutrons and protons oscillate in the direction of the photon electric field. The oscillation is damped by friction in a few cycles, with the photon energy being transfered to the nucleus in a process similar to evaporation. Nucleons emitted in the dipolar interaction have an anisotropic angular distribution, with a maximum at 90°, while those leaving the nucleus as a result of evaporation are emitted isotropically with a Maxwellian energy distribution described as [6]:

$$\frac{dN}{dE_n} = \frac{E_n}{T^2} e^{-E_n/T} \ , \tag{33.4} \label{eq:33.4}$$

where T is a nuclear 'temperature' (in units of MeV) characteristic of the particular target nucleus and its excitation energy. For heavy nuclei the 'temperature' generally lies in the range of T=0.5–1.0 MeV. For higher energy photons, the quasi-deuteron (between about 30 MeV and 250 MeV), delta resonance (250 MeV–1.2 GeV) and vector meson dominance ($\gtrsim 1.2$ GeV) mechanisms become important.

Neutron yields from semi-infinite targets per kW of electron beam power are plotted in Fig. 33.2 as a function of the electron beam energy [6].

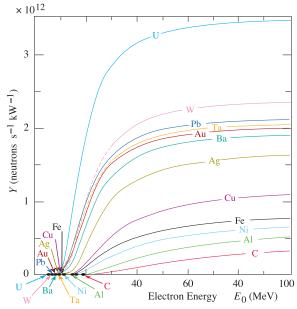

Figure 33.2: Neutron yields from semi-infinite targets per kW of electron beam power, as a function of the electron beam energy, disregarding target self-shielding [6].

Typical neutron energy spectra outside of concrete (80 cm thick, $2.35~{\rm g/cm^3}$) and iron (40 cm thick) shields are shown in Fig. 33.3. In order to compare these spectra to those caused by proton beams (see below) the spectra are scaled by a factor of 100, which roughly corresponds to the difference in the high energy hadronic cross sections for photons and hadrons (e.g., the fine structure constant). The shape of these spectra are generally characterized by a low-energy peak at around 1 MeV (evaporation neutrons) and a high-energy shoulder at around 70–80 MeV. In case of concrete shielding, the spectrum also shows a pronounced peak at thermal neutron energies.

 $^{^{\}dagger}$ RBE-weighted when necessary

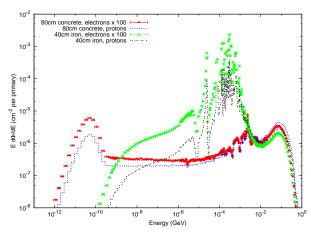

Figure 33.3: Neutron energy spectra calculated with the FLUKA code [7,8] from 25 GeV proton and electron beams on a thick copper target. Spectra are evaluated at 90° to the beam direction behind 80 cm of concrete or 40 cm of iron. All spectra are normalized per beam particle. In addition, spectra for electron beam are multiplied by a factor of 100.

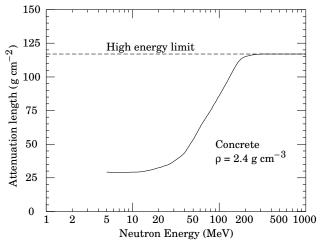

Figure 33.4: The variation of the attenuation length for mono-energetic neutrons in concrete as a function of neutron energy [9].

${\bf 33.4.2.} \quad Proton\ accelerators:$

At proton accelerators, neutron yields emitted per incident proton by different target materials are roughly independent of proton energy between 20 MeV and 1 GeV, and are given by the ratio C: Al: Cu-Fe: Sn: Ta-Pb = 0.3:0.6:1.0:1.5:1.7 [9]. Above about 1 GeV, the neutron yield is proportional to E^m , where $0.80 \le m \le 0.85$ [10].

Typical neutron energy spectra outside of concrete and iron shielding are shown in Fig. 33.3. Here, the radiation fields are caused by a 25 GeV proton beam interacting with a thick copper target. The comparison of these spectra with those for an electron beam of the same energy reflects the difference in the hadronic cross sections between photons and hadrons above a few 100 MeV. Differences are increasing towards lower energies because of different interaction mechanisms. Furthermore, the slight shift in energy above about 100 MeV follows from the fact that the energies of the interacting photons are lower than 25 GeV. Apart from this the shapes of the two spectra are similar.

The neutron-attenuation length is shown in Fig. 33.4 for concrete and mono-energetic broad-beam conditions. As can be seen in the figure it reaches a value of about $117~\rm g/cm^2$ above 200 MeV. As the cascade through thick shielding is carried by high-energy particles this value is equal to the equilibrium attenuation length at 90 degrees in concrete.

33.5. Photon sources

The dose equivalent rate in tissue (in mSv/h) from a gamma point source emitting one photon of energy E (in MeV) per second at a distance of 1 m is $4.6 \times 10^{-9} \, \mu_{en}/\rho \, E$, where μ_{en}/ρ is the mass energy absorption coefficient. The latter has a value of $0.029 \pm 0.004 \, \mathrm{cm}^2/\mathrm{g}$ for photons in tissue over an energy range between 60 keV and 2 MeV (see Ref. 11 for tabulated values).

Similarly, the dose equivalent rate in tissue (in mSv/h) at the surface of a semi-infinite slab of uniformly activated material containing 1 Bq/g of a gamma emitter of energy E (in MeV) is $2.9 \times 10^{-4} R_{\mu} E$, where R_{μ} is the ratio of the mass energy absorption coefficients of the photons in tissue and in the material.

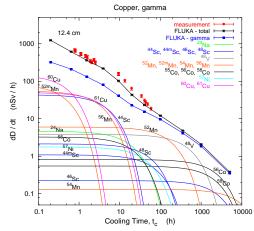

Figure 33.5: Contribution of individual gamma-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [12].

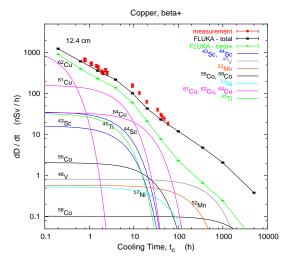

Figure 33.6: Contribution of individual positron-emitting nuclides to the total dose rate at 12.4 cm distance to an activated copper sample [12].

33.6. Accelerator-induced radioactivity

Typical medium- and long-lived activation products in metallic components of accelerators are 22 Na, 46 Sc, 48 V, 51 Cr, 54 Mn, 55 Fe, 59 Fe, 56 Co, 57 Co, 58 Co, 60 Co, 63 Ni and 65 Zn. Gamma-emitting nuclides dominate doses by external irradiation at longer decay times (more than one day) while at short decay times β^+ emitters are also important (through photons produced by β^+ annihilation). Due to their short range, β^- emitters are relevant, for example, only for

dose to the skin and eyes or for doses due to inhalation or ingestion. Fig. 33.5 and Fig. 33.6 show the contributions of gamma and β^+ emitters to the total dose rate at 12.4 cm distance to an activated copper sample [12]. Typically, dose rates at a certain decay time are mainly determined by radionuclides having a half-life of the order of the decay time. Extended irradiation periods might be an exception to this general rule as in this case the activity of long-lived nuclides can built up sufficiently so that it dominates that one of short-lived even at short cooling times.

Activation in concrete is dominated by 24 Na (short decay times) and 22 Na (long decay times). Both nuclides can be produced either by low-energy neutron reactions on the sodium-component in the concrete or by spallation reactions on silicon and calcium. At long decay times nuclides of radiological interest in activated concrete can also be 60 Co, 152 Eu, 154 Eu and 134 Cs, all of which produced by (n,γ) -reactions with traces of natural cobalt, europium and cesium, Thus, such trace elements might be important even if their content in concrete is only a few parts per million or less by weight.

The explicit simulation of radionuclide production with general-purpose Monte Carlo codes has become the most commonly applied method to calculate induced radioactivity and its radiological consequences. Nevertheless, other more approximative approaches, such as " ω -factors" [9], can still be useful for fast order-of-magnitude estimates. These ω -factors give the dose rate per unit star density (inelastic reactions above a certain energy threshold, e.g. 50 MeV) on contact to an extended, uniformly activated object after a 30-day irradiation and 1-day decay. For steel or iron, $\omega \simeq 3 \times 10^{-12}$ (Sv cm³/star). This does not include possible contributions from thermal-neutron activation.

"Emission probability" is the probability per decay of a given emission; because of cascades these may total more than 100%. Only principal emissions are listed. EC means electron capture, and e^- means monoenergetic internal conversion (Auger) electron. The intensity of 0.511 MeV e^+e^- annihilation photons depends upon the number of stopped positrons. Endpoint β^\pm energies are listed. In some cases when energies are closely spaced, the γ -ray values are approximate weighted averages. Radiation from short-lived daughter isotopes is included where relevant.

Half-lives, energies, and intensities are from E. Browne and R.B. Firestone, *Table of Radioactive Isotopes* (John Wiley & Sons, New York, 1986), recent *Nuclear Data Sheets*, and *X-ray and Gamma-ray Standards for Detector Calibration*, IAEA-TECDOC-619 (1991).

Neutron data are from Neutron Sources for Basic Physics and Applications (Pergamon Press, 1983).

35. PROBABILITY

Revised September 2011 by G. Cowan (RHUL).

35.1. General [1–8]

An abstract definition of probability can be given by considering a set S, called the sample space, and possible subsets A, B, \ldots , the interpretation of which is left open. The probability P is a real-valued function defined by the following axioms due to Kolmogorov [9]:

- 1. For every subset A in S, $P(A) \ge 0$;
- 2. For disjoint subsets (i.e., $A \cap B = \emptyset$), $P(A \cup B) = P(A) + P(B)$;
- 3. P(S) = 1.

In addition, one defines the conditional probability P(A|B) (read P of A given B) as

$$P(A|B) = \frac{P(A \cap B)}{P(B)}. \tag{35.1}$$

From this definition and using the fact that $A \cap B$ and $B \cap A$ are the same, one obtains Bayes' theorem,

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}$$
 (35.2)

From the three axioms of probability and the definition of conditional probability, one obtains the law of total probability,

$$P(B) = \sum_{i} P(B|A_i)P(A_i) ,$$
 (35.3)

for any subset B and for disjoint A_i with $\bigcup_i A_i = S$. This can be combined with Bayes' theorem (Eq. (35.2)) to give

$$P(A|B) = \frac{P(B|A)P(A)}{\sum_{i} P(B|A_{i})P(A_{i})},$$
 (35.4)

where the subset A could, for example, be one of the A_i .

The most commonly used interpretation of the subsets of the sample space are outcomes of a repeatable experiment. The probability P(A)is assigned a value equal to the limiting frequency of occurrence of A. This interpretation forms the basis of frequentist statistics.

The subsets of the sample space can also be interpreted as hypotheses, i.e., statements that are either true or false, such as 'The mass of the W boson lies between 80.3 and 80.5 GeV.' In the frequency interpretation, such statements are either always or never true, i.e., the corresponding probabilities would be 0 or 1. Using subjective probability, however, P(A) is interpreted as the degree of belief that the hypothesis A is true. Subjective probability is used in Bayesian (as opposed to frequentist) statistics. Bayes' theorem can be written

$$P(\text{theory}|\text{data}) \propto P(\text{data}|\text{theory})P(\text{theory})$$
, (35.5)

where 'theory' represents some hypothesis and 'data' is the outcome of the experiment. Here P(theory) is the *prior* probability for the theory, which reflects the experimenter's degree of belief before carrying out the measurement, and P(data|theory) is the probability to have gotten the data actually obtained, given the theory, which is also called the likelihood.

Bayesian statistics provides no fundamental rule for obtaining the prior probability, which may depend on previous measurements, theoretical prejudices, etc. Once this has been specified, however, Eq. (35.5) tells how the probability for the theory must be modified in the light of the new data to give the posterior probability, P(theory|data). As Eq. (35.5) is stated as a proportionality, the probability must be normalized by summing (or integrating) over all possible hypotheses.

35.2. Random variables

A random variable is a numerical characteristic assigned to an element of the sample space. In the frequency interpretation of probability, it corresponds to an outcome of a repeatable experiment. Let x be a possible outcome of an observation. If x can take on any value from a continuous range, we write $f(x;\theta)dx$ as the probability that the measurement's outcome lies between x and x + dx. The function $f(x;\theta)$ is called the *probability density function* (p.d.f.), which may depend on one or more parameters θ . If x can take on only discrete values (e.g., the non-negative integers), then $f(x;\theta)$ is itself a probability.

The p.d.f. is always normalized to unit area (unit sum, if discrete). Both x and θ may have multiple components and are then often written as vectors. If θ is unknown, we may wish to estimate its value from a given set of measurements of x; this is a central topic of statistics (see Sec. 36).

The cumulative distribution function F(a) is the probability that

$$F(a) = \int_{-\infty}^{a} f(x) \, dx \,. \tag{35.6}$$

Here and below, if x is discrete-valued, the integral is replaced by a sum. The endpoint a is expressly included in the integral or sum. Then $0 \le F(x) \le 1$, F(x) is nondecreasing, and $P(a < x \le b) = F(b) - F(a)$. If x is discrete, F(x) is flat except at allowed values of x, where it has discontinuous jumps equal to f(x).

Any function of random variables is itself a random variable, with (in general) a different p.d.f. The expectation value of any function u(x) is

$$E[u(x)] = \int_{-\infty}^{\infty} u(x) f(x) dx , \qquad (35.7)$$

assuming the integral is finite. For u(x) and v(x), any two functions of x, E[u+v] = E[u] + E[v]. For c and k constants, E[cu+k] = cE[u] + k. The n^{th} moment of a random variable x is

$$\alpha_n \equiv E[x^n] = \int_{-\infty}^{\infty} x^n f(x) dx$$
, (35.8a)

and the n^{th} central moment of x (or moment about the mean, $\alpha_1)$ is

$$m_n \equiv E[(x - \alpha_1)^n] = \int_{-\infty}^{\infty} (x - \alpha_1)^n f(x) dx$$
. (35.8b)

The most commonly used moments are the mean μ and variance σ^2 :

$$\mu \equiv \alpha_1$$
, (35.9a)

$$\mu \equiv \alpha_1 , \qquad (35.9a)$$

$$\sigma^2 \equiv V[x] \equiv m_2 = \alpha_2 - \mu^2 . \qquad (35.9b)$$

The mean is the location of the "center of mass" of the p.d.f., and the variance is a measure of the square of its width. Note that $V[cx+k] = c^2V[x]$. It is often convenient to use the standard deviation of x, σ , defined as the square root of the variance.

Any odd moment about the mean is a measure of the skewness of the p.d.f. The simplest of these is the dimensionless coefficient of skewness $\gamma_1 = m_3/\sigma^3$.

The fourth central moment m_4 provides a convenient measure of the tails of a distribution. For the Gaussian distribution (see Sec. 35.4), one has $m_4 = 3\sigma^4$. The kurtosis is defined as $\gamma_2 = m_4/\sigma^4 - 3$, i.e., it is zero for a Gaussian, positive for a leptokurtic distribution with longer tails, and negative for a platykurtic distribution with tails that die off more quickly than those of a Gaussian.

The quantile x_{α} is the value of the random variable x at which the cumulative distribution is equal to α . That is, the quantile is the inverse of the cumulative distribution function, i.e., $x_{\alpha} = F^{-1}(\alpha)$. An important special case is the median, x_{med} , defined by $F(x_{\text{med}}) = 1/2$, i.e., half the probability lies above and half lies below x_{med} . (More rigorously, $x_{\rm med}$ is a median if $P(x \ge x_{\rm med}) \ge 1/2$ and $P(x \le x_{\text{med}}) \ge 1/2$. If only one value exists, it is called 'the median.')

Under a monotonic change of variable $x \to y(x)$, the quantiles of a distribution (and hence also the median) obey $y_{\alpha} = y(x_{\alpha})$. In general the expectation value and *mode* (most probable value) of a distribution do not, however, transform in this way.

Let x and y be two random variables with a *joint* p.d.f. f(x, y). The *marginal* p.d.f. of x (the distribution of x with y unobserved) is

$$f_1(x) = \int_{-\infty}^{\infty} f(x, y) \, dy$$
, (35.10)

and similarly for the marginal p.d.f. $f_2(y)$. The conditional p.d.f. of y given fixed x (with $f_1(x) \neq 0$) is defined by $f_3(y|x) = f(x,y)/f_1(x)$, and similarly $f_4(x|y) = f(x,y)/f_2(y)$. From these, we immediately obtain Bayes' theorem (see Eqs. (35.2) and (35.4)),

$$f_4(x|y) = \frac{f_3(y|x)f_1(x)}{f_2(y)} = \frac{f_3(y|x)f_1(x)}{\int f_3(y|x')f_1(x') dx'}.$$
 (35.11)

The mean of x is

$$\mu_x = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} x f(x, y) dx dy = \int_{-\infty}^{\infty} x f_1(x) dx, \qquad (35.12)$$

and similarly for y. The covariance of x and y is

$$cov[x, y] = E[(x - \mu_x)(y - \mu_y)] = E[xy] - \mu_x \mu_y.$$
 (35.13)

A dimensionless measure of the covariance of x and y is given by the correlation coefficient,

$$\rho_{xy} = \text{cov}[x, y] / \sigma_x \sigma_y , \qquad (35.14)$$

where σ_x and σ_y are the standard deviations of x and y. It can be shown that $-1 \le \rho_{xy} \le 1$.

Two random variables x and y are *independent* if and only if

$$f(x,y) = f_1(x)f_2(y)$$
. (35.15)

If x and y are independent, then $\rho_{xy}=0$; the converse is not necessarily true. If x and y are independent, E[u(x)v(y)]=E[u(x)]E[v(y)], and V[x+y]=V[x]+V[y]; otherwise, $V[x+y]=V[x]+V[y]+2\mathrm{cov}[x,y]$, and E[uv] does not necessarily factorize.

Consider a set of n continuous random variables $\mathbf{x} = (x_1, \dots, x_n)$ with joint p.d.f. $f(\mathbf{x})$, and a set of n new variables $\mathbf{y} = (y_1, \dots, y_n)$, related to \mathbf{x} by means of a function $\mathbf{y}(\mathbf{x})$ that is one-to-one, *i.e.*, the inverse $\mathbf{x}(\mathbf{y})$ exists. The joint p.d.f. for \mathbf{y} is given by

$$g(\mathbf{y}) = f(\mathbf{x}(\mathbf{y}))|J| \quad , \tag{35.16}$$

where |J| is the absolute value of the determinant of the square matrix $J_{ij} = \partial x_i/\partial y_j$ (the Jacobian determinant). If the transformation from \boldsymbol{x} to \boldsymbol{y} is not one-to-one, the \boldsymbol{x} -space must be broken into regions where the function $\boldsymbol{y}(\boldsymbol{x})$ can be inverted, and the contributions to $g(\boldsymbol{y})$ from each region summed.

Given a set of functions $\boldsymbol{y} = (y_1, \dots, y_m)$ with m < n, one can construct n-m additional independent functions, apply the procedure above, then integrate the resulting $g(\boldsymbol{y})$ over the unwanted y_i to find the marginal distribution of those of interest.

For a one-to-one transformation of discrete random variables, simply substitute; no Jacobian is necessary because now f is a probability rather than a probability density. If the transformation is not one-to-one, then sum the probabilities for all values of the original variable that contribute to a given value of the transformed variable. If f depends on a set of parameters θ , a change to a different parameter set $\eta(\theta)$ is made by simple substitution; no Jacobian is used.

35.3. Characteristic functions

The characteristic function $\phi(u)$ associated with the p.d.f. f(x) is essentially its Fourier transform, or the expectation value of e^{iux} :

$$\phi(u) = E\left[e^{iux}\right] = \int_{-\infty}^{\infty} e^{iux} f(x) dx. \qquad (35.17)$$

Once $\phi(u)$ is specified, the p.d.f. f(x) is uniquely determined and vice versa; knowing one is equivalent to the other. Characteristic functions are useful in deriving a number of important results about moments and sums of random variables.

It follows from Eqs. (35.8a) and (35.17) that the n^{th} moment of a random variable x that follows f(x) is given by

$$i^{-n} \frac{d^n \phi}{du^n}\Big|_{u=0} = \int_{-\infty}^{\infty} x^n f(x) dx = \alpha_n.$$
 (35.18)

Thus it is often easy to calculate all the moments of a distribution defined by $\phi(u)$, even when f(x) cannot be written down explicitly.

If the p.d.f.s $f_1(x)$ and $f_2(y)$ for independent random variables x and y have characteristic functions $\phi_1(u)$ and $\phi_2(u)$, then the characteristic function of the weighted sum ax + by is $\phi_1(au)\phi_2(bu)$. The rules of addition for several important distributions (e.g., that the sum of two Gaussian distributed variables also follows a Gaussian distribution) easily follow from this observation.

Let the (partial) characteristic function corresponding to the conditional p.d.f. $f_2(x|z)$ be $\phi_2(u|z)$, and the p.d.f. of z be $f_1(z)$. The characteristic function after integration over the conditional value is

$$\phi(u) = \int \phi_2(u|z) f_1(z) dz . {(35.19)}$$

Suppose we can write ϕ_2 in the form

$$\phi_2(u|z) = A(u)e^{ig(u)z}$$
 (35.20)

Then

$$\phi(u) = A(u)\phi_1(g(u)) . (35.21)$$

The cumulants (semi-invariants) κ_n of a distribution with characteristic function $\phi(u)$ are defined by the relation

$$\phi(u) = \exp\left[\sum_{n=1}^{\infty} \frac{\kappa_n}{n!} (iu)^n\right] = \exp\left(i\kappa_1 u - \frac{1}{2}\kappa_2 u^2 + \dots\right) . \quad (35.22)$$

The values κ_n are related to the moments α_n and m_n . The first few relations are

$$\begin{split} \kappa_1 &= \alpha_1 \ (= \mu, \ \text{the mean}) \\ \kappa_2 &= m_2 \ = \alpha_2 - \alpha_1^2 \ (= \sigma^2, \ \text{the variance}) \\ \kappa_3 &= m_3 = \alpha_3 - 3\alpha_1\alpha_2 + 2\alpha_1^3 \ . \end{split} \tag{35.23}$$

35.4. Some probability distributions

Table 35.1 gives a number of common probability density functions and corresponding characteristic functions, means, and variances. Further information may be found in Refs. [1–8], [17], and [11], which has particularly detailed tables. Monte Carlo techniques for generating each of them may be found in our Sec. 37.4 and in Ref. 17. We comment below on all except the trivial uniform distribution.

35.4.1. Binomial distribution:

A random process with exactly two possible outcomes which occur with fixed probabilities is called a *Bernoulli* process. If the probability of obtaining a certain outcome (a "success") in an individual trial is p, then the probability of obtaining exactly r successes $(r=0,1,2,\ldots,N)$ in N independent trials, without regard to the order of the successes and failures, is given by the binomial distribution f(r;N,p) in Table 35.1. If r and s are binomially distributed with parameters (N_r,p) and (N_s,p) , then t=r+s follows a binomial distribution with parameters (N_r+N_s,p) .

Table 35.1. Some common probability density functions, with corresponding characteristic functions and means and variances. In the Table, $\Gamma(k)$ is the gamma function, equal to (k-1)! when k is an integer; ${}_1F_1$ is the confluent hypergeometric function of the 1st kind [11].

| Distribution | Probability density function f (variable; parameters) | Characteristic function $\phi(u)$ | Mean | Variance σ^2 |
|--------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------|------------------------------------------------------|--------------------------------------------------------|
| Uniform | $f(x; a, b) = \begin{cases} 1/(b-a) & a \le x \le b \\ 0 & \text{otherwise} \end{cases}$ | $\frac{e^{ibu} - e^{iau}}{(b-a)iu}$ | $\frac{a+b}{2}$ | $\frac{(b-a)^2}{12}$ |
| Binomial | $f(r; N, p) = \frac{N!}{r!(N-r)!} p^r q^{N-r}$ $r = 0, 1, 2, \dots, N ; 0 \le p \le 1 ; q = 1-p$ | $(q + pe^{iu})^N$ | Np | Npq |
| Poisson | $f(n;\nu) = \frac{\nu^n e^{-\nu}}{n!}$; $n = 0, 1, 2,$; $\nu > 0$ | $\exp[\nu(e^{iu}-1)]$ | ν | ν |
| Normal (Gaussian) | $f(x; \mu, \sigma^2) = \frac{1}{\sigma\sqrt{2\pi}} \exp(-(x - \mu)^2/2\sigma^2)$ $-\infty < x < \infty \; ; -\infty < \mu < \infty \; ; \sigma > 0$ | $\exp(i\mu u - \frac{1}{2}\sigma^2 u^2)$ | μ | σ^2 |
| Multivariate Gaussian | $f(\boldsymbol{x}; \boldsymbol{\mu}, V) = \frac{1}{(2\pi)^{n/2} \sqrt{ V }}$ $\times \exp\left[-\frac{1}{2} (\boldsymbol{x} - \boldsymbol{\mu})^T V^{-1} (\boldsymbol{x} - \boldsymbol{\mu})\right]$ | $\exp\left[i\boldsymbol{\mu}\cdot\boldsymbol{u}-\frac{1}{2}\boldsymbol{u}^TV\boldsymbol{u}\right]$ | μ | V_{jk} |
| χ^2 | $-\infty < x_j < \infty; -\infty < \mu_j < \infty; V > 0$ $f(z;n) = \frac{z^{n/2 - 1} e^{-z/2}}{2^{n/2} \Gamma(n/2)}; z \ge 0$ | $(1-2iu)^{-n/2}$ | n | 2n |
| Student's t | $f(t;n) = \frac{1}{\sqrt{n\pi}} \frac{\Gamma[(n+1)/2]}{\Gamma(n/2)} \left(1 + \frac{t^2}{n}\right)^{-(n+1)/2}$ $-\infty < t < \infty ; \qquad n \text{ not required to be integer}$ | - | $ \begin{cases} 0 \\ \text{for } n > 1 \end{cases} $ | n/(n-2) for $n > 2$ |
| Gamma | $f(x;\lambda,k) = \frac{x^{k-1}\lambda^k e^{-\lambda x}}{\Gamma(k)}\;; \qquad 0 \le x < \infty\;;$ $k \text{ not required to be integer}$ | $(1 - iu/\lambda)^{-k}$ | k/λ | k/λ^2 |
| Beta | $f(x; \alpha, \beta) = \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} x^{\alpha - 1} (1 - x)^{\beta - 1}$ $0 \le x \le 1$ | $_1F_1(\alpha;\alpha+\beta;iu)$ | $\frac{\alpha}{\alpha + \beta}$ | $\frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$ |

35.4.2. Poisson distribution:

The Poisson distribution $f(n;\nu)$ gives the probability of finding exactly n events in a given interval of x (e.g., space or time) when the events occur independently of one another and of x at an average rate of ν per the given interval. The variance σ^2 equals ν . It is the limiting case $p \to 0$, $N \to \infty$, $Np = \nu$ of the binomial distribution. The Poisson distribution approaches the Gaussian distribution for large ν .

For example, a large number of radioactive nuclei of a given type will result in a certain number of decays in a fixed time interval. If this interval is small compared to the mean lifetime, then the probability for a given nucleus to decay is small, and thus the number of decays in the time interval is well modeled as a Poisson variable.

35.4.3. Normal or Gaussian distribution:

The normal (or Gaussian) probability density function $f(x; \mu, \sigma^2)$ given in Table 35.1 has mean $E[x] = \mu$ and variance $V[x] = \sigma^2$. Comparison of the characteristic function $\phi(u)$ given in Table 35.1 with Eq. (35.22) shows that all cumulants κ_n beyond κ_2 vanish; this is a unique property of the Gaussian distribution. Some other properties are:

 $P(x \text{ in range } \mu \pm \sigma) = 0.6827,$

 $P(x \text{ in range } \mu \pm 0.6745\sigma) = 0.5,$

$$E[|x - \mu|] = \sqrt{2/\pi}\sigma = 0.7979\sigma,$$

half-width at half maximum = $\sqrt{2 \ln 2} \sigma = 1.177 \sigma$.

For a Gaussian with $\mu=0$ and $\sigma^2=1$ (the *standard* Gaussian), the cumulative distribution, Eq. (35.6), is related to the error function $\operatorname{erf}(y)$ by

$$F(x;0,1) = \frac{1}{2} \left[1 + \text{erf}(x/\sqrt{2}) \right]$$
 (35.24)

The error function and standard Gaussian are tabulated in many references (e.g., Ref. [11,12]) and are available in software packages such as ROOT [5]. For a mean μ and variance σ^2 , replace x by $(x-\mu)/\sigma$. The probability of x in a given range can be calculated with Eq. (36.55).

For x and y independent and normally distributed, z = ax + by follows $f(z; a\mu_x + b\mu_y, a^2\sigma_x^2 + b^2\sigma_y^2)$; that is, the weighted means and variances add.

The Gaussian derives its importance in large part from the central $limit\ theorem$:

If independent random variables x_1, \ldots, x_n are distributed according to any p.d.f. with finite mean and variance, then the sum $y = \sum_{i=1}^n x_i$ will have a p.d.f. that approaches a Gaussian for large n. If the p.d.f.s of the x_i are not identical, the theorem still holds under somewhat more restrictive conditions. The mean and variance are given by the sums of corresponding terms from the individual x_i . Therefore, the sum of a large number of fluctuations x_i will be distributed as a Gaussian, even if the x_i themselves are not.

(Note that the product of a large number of random variables is not Gaussian, but its logarithm is. The p.d.f. of the product is log-normal. See Ref. 8 for details.)

For a set of n Gaussian random variables x with means μ and covariances $V_{ij}=\text{cov}[x_i,x_j],$ the p.d.f. for the one-dimensional

Gaussian is generalized to

$$f(x; \mu, V) = \frac{1}{(2\pi)^{n/2} \sqrt{|V|}} \exp\left[-\frac{1}{2}(x - \mu)^T V^{-1}(x - \mu)\right], \quad (35.25)$$

where the determinant |V| must be greater than 0. For diagonal V (independent variables), $f(x; \mu, V)$ is the product of the p.d.f.s of n Gaussian distributions. For n = 2, $f(x; \mu, V)$ is

$$f(x_1, x_2; \ \mu_1, \mu_2, \sigma_1, \sigma_2, \rho) = \frac{1}{2\pi\sigma_1\sigma_2\sqrt{1-\rho^2}} \ \times$$

$$\exp\left\{\frac{-1}{2(1-\rho^2)}\left[\frac{(x_1-\mu_1)^2}{\sigma_1^2} - \frac{2\rho(x_1-\mu_1)(x_2-\mu_2)}{\sigma_1\sigma_2} + \frac{(x_2-\mu_2)^2}{\sigma_2^2}\right]\right\}.$$
(35.26)

The characteristic function for the multivariate Gaussian is

$$\phi(\boldsymbol{u}; \boldsymbol{\mu}, V) = \exp\left[i\boldsymbol{\mu} \cdot \boldsymbol{u} - \frac{1}{2}\boldsymbol{u}^T V \boldsymbol{u}\right].$$
 (35.27)

If the components of \boldsymbol{x} are independent, then Eq. (35.27) is the product of the c.f.s of n Gaussians.

For a multi-dimensional Gaussian distribution for variables x_i , $i=1,\ldots,n$, the marginal distribution for any single x_i is is a one-dimensional Gaussian with mean μ_i and variance V_{ii} . V is $n\times n$, symmetric, and positive definite. For any vector \boldsymbol{X} , the quadratic form $\boldsymbol{X}^TV^{-1}\boldsymbol{X}=C$, where C is any positive number, traces an n-dimensional ellipsoid as \boldsymbol{X} varies. If $X_i=x_i-\mu_i$, then C is a random variable obeying the χ^2 distribution with n degrees of freedom, discussed in the following section. The probability that \boldsymbol{X} corresponding to a set of Gaussian random variables x_i lies outside the ellipsoid characterized by a given value of C (= χ^2) is given by $1-F_{\chi^2}(C;n)$, where F_{χ^2} is the cumulative χ^2 distribution. This may be read from Fig. 36.1. For example, the "s-standard-deviation ellipsoid" occurs at $C=s^2$. For the two-variable case (n=2), the point \boldsymbol{X} lies outside the one-standard-deviation ellipsoid with 61% probability. The use of these ellipsoids as indicators of probable error is described in Sec. 36.3.2.4; the validity of those indicators assumes that $\boldsymbol{\mu}$ and V are correct.

35.4.4. χ^2 distribution:

If x_1,\ldots,x_n are independent Gaussian random variables, the sum $z=\sum_{i=1}^n(x_i-\mu_i)^2/\sigma_i^2$ follows the χ^2 p.d.f. with n degrees of freedom, which we denote by $\chi^2(n)$. More generally, for n correlated Gaussian variables as components of a vector \boldsymbol{X} with covariance matrix V, $z=\boldsymbol{X}^TV^{-1}\boldsymbol{X}$ follows $\chi^2(n)$ as in the previous section. For a set of z_i , each of which follows $\chi^2(n_i)$, $\sum z_i$ follows $\chi^2(\sum n_i)$. For large n, the χ^2 p.d.f. approaches a Gaussian with a mean and variance give by $\mu=n$ and $\sigma^2=2n$, respectively (here the formulae for μ and σ^2 are valid for all n).

The χ^2 p.d.f. is often used in evaluating the level of compatibility between observed data and a hypothesis for the p.d.f. that the data might follow. This is discussed further in Sec. 36.2.2 on tests of goodness-of-fit.

${\bf 35.4.5.} \quad \textit{Student's t distribution}:$

Suppose that y and x_1, \ldots, x_n are independent and Gaussian distributed with mean 0 and variance 1. We then define

$$z = \sum_{i=1}^{n} x_i^2$$
 and $t = \frac{y}{\sqrt{z/n}}$. (35.28)

The variable z thus follows a $\chi^2(n)$ distribution. Then t is distributed according to Student's t distribution with n degrees of freedom, f(t;n), given in Table 35.1.

The Student's t distribution resembles a Gaussian but has wider tails. As $n\to\infty$, the distribution approaches a Gaussian. If n=1, it is a Cauchy or Breit-Wigner distribution. This distribution is symmetric about zero (its mode), but the expectation value is undefined. For the Student's t, the mean is well defined only for n>1 and the variance is finite only for n>2, so the central limit theorem is

not applicable to sums of random variables following the t distribution for n=1 or 2.

As an example, consider the sample mean $\overline{x} = \sum x_i/n$ and the sample variance $s^2 = \sum (x_i - \overline{x})^2/(n-1)$ for normally distributed x_i with unknown mean μ and variance σ^2 . The sample mean has a Gaussian distribution with a variance σ^2/n , so the variable $(\overline{x} - \mu)/\sqrt{\sigma^2/n}$ is normal with mean 0 and variance 1. The quantity $(n-1)s^2/\sigma^2$ is independent of this and follows $\chi^2(n-1)$. The ratio

$$t = \frac{(\overline{x} - \mu)/\sqrt{\sigma^2/n}}{\sqrt{(n-1)s^2/\sigma^2(n-1)}} = \frac{\overline{x} - \mu}{\sqrt{s^2/n}}$$
 (35.29)

is distributed as f(t;n-1). The unknown variance σ^2 cancels, and t can be used to test the hypothesis that the true mean is some particular value μ .

In Table 35.1, n in f(t;n) is not required to be an integer. A Student's t distribution with non-integral n>0 is useful in certain applications.

35.4.6. Gamma distribution:

For a process that generates events as a function of x (e.g., space or time) according to a Poisson distribution, the distance in x from an arbitrary starting point (which may be some particular event) to the k^{th} event follows a gamma distribution, $f(x; \lambda, k)$. The Poisson parameter μ is λ per unit x. The special case k = 1 (i.e., $f(x; \lambda, 1) = \lambda e^{-\lambda x}$) is called the exponential distribution. A sum of k' exponential random variables x_i is distributed as $f(\sum x_i; \lambda, k')$.

The parameter k is not required to be an integer. For $\lambda=1/2$ and k=n/2, the gamma distribution reduces to the $\chi^2(n)$ distribution.

$35.4.7. \ Beta \ distribution:$

The beta distribution describes a continuous random variable x in the interval [0,1]; this can easily be generalized by scaling and translation to have arbitrary endpoints. In Bayesian inference about the parameter p of a binomial process, if the prior p.d.f. is a beta distribution $f(p;\alpha,\beta)$ then the observation of r successes out of N trials gives a posterior beta distribution $f(p;r+\alpha,N-r+\beta)$ (Bayesian methods are discussed further in Sec. 36). The uniform distribution is a beta distribution with $\alpha=\beta=1$.

36. STATISTICS

Revised September 2011 by G. Cowan (RHUL).

This chapter gives an overview of statistical methods used in high-energy physics. In statistics, we are interested in using a given sample of data to make inferences about a probabilistic model, e.g., to assess the model's validity or to determine the values of its parameters. There are two main approaches to statistical inference, which we may call frequentist and Bayesian. In frequentist statistics, probability is interpreted as the frequency of the outcome of a repeatable experiment. The most important tools in this framework are parameter estimation, covered in Section 36.1, and statistical tests, discussed in Section 36.2. Frequentist confidence intervals, which are constructed so as to cover the true value of a parameter with a specified probability, are treated in Section 36.3.2. Note that in frequentist statistics one does not define a probability for a hypothesis or for a parameter.

Frequentist statistics provides the usual tools for reporting the outcome of an experiment objectively, without needing to incorporate prior beliefs concerning the parameter being measured or the theory being tested. As such, they are used for reporting most measurements and their statistical uncertainties in high-energy physics.

In Bayesian statistics, the interpretation of probability is more general and includes degree of belief (called subjective probability). One can then speak of a probability density function (p.d.f.) for a parameter, which expresses one's state of knowledge about where its true value lies. Bayesian methods allow for a natural way to input additional information, which in general may be subjective; in fact they require the prior p.d.f. as input for the parameters, i.e., the degree of belief about the parameters' values before carrying out the measurement. Using Bayes' theorem Eq. (35.4), the prior degree of belief is updated by the data from the experiment. Bayesian methods for interval estimation are discussed in Sections 36.3.1 and 36.3.2.6

Bayesian techniques are often used to treat systematic uncertainties, where the author's beliefs about, say, the accuracy of the measuring device may enter. Bayesian statistics also provides a useful framework for discussing the validity of different theoretical interpretations of the data. This aspect of a measurement, however, will usually be treated separately from the reporting of the result. In some analyses, both the frequentist and Bayesian approaches are used together. One may, for example, treat systematic uncertainties in a model using Bayesian methods, but then construct a frequentist statistical test of that model.

For many inference problems, the frequentist and Bayesian approaches give similar numerical answers, even though they are based on fundamentally different interpretations of probability. For small data samples, however, and for measurements of a parameter near a physical boundary, the different approaches may yield different results, so we are forced to make a choice. For a discussion of Bayesian vs. non-Bayesian methods, see references written by a statistician [1], by a physicist [2], or the more detailed comparison in Ref. 3.

Following common usage in physics, the word "error" is often used in this chapter to mean "uncertainty." More specifically it can indicate the size of an interval as in "the standard error" or "error propagation," where the term refers to the standard deviation of an estimator.

36.1. Parameter estimation

Here we review *point estimation* of parameters, first with an overview of the frequentist approach and its two most important methods, maximum likelihood and least squares, treated in Sections 36.1.2 and 36.1.3. The Bayesian approach is outlined in Sec. 36.1.4.

An estimator θ (written with a hat) is a function of the data used to estimate the value of the parameter θ . Sometimes the word 'estimate' is used to denote the value of the estimator when evaluated with given data. There is no fundamental rule dictating how an estimator must be constructed. One tries, therefore, to choose that estimator which has the best properties. The most important of these are (a) consistency, (b) bias, (c) efficiency, and (d) robustness.

(a) An estimator is said to be *consistent* if the estimate $\hat{\theta}$ converges to the true value θ as the amount of data increases. This property is so important that it is possessed by all commonly used estimators.

(b) The bias, $b=E[\widehat{\theta}]-\theta$, is the difference between the expectation value of the estimator and the true value of the parameter. The expectation value is taken over a hypothetical set of similar experiments in which $\widehat{\theta}$ is constructed in the same way. When b=0, the estimator is said to be unbiased. The bias depends on the chosen metric, i.e., if $\widehat{\theta}$ is an unbiased estimator of θ , then $\widehat{\theta}^2$ is not in general an unbiased estimator for θ^2 . If we have an estimate \widehat{b} for the bias, we can subtract it from $\widehat{\theta}$ to obtain a new $\widehat{\theta}'=\widehat{\theta}-\widehat{b}$. The estimate \widehat{b} may, however, be subject to statistical or systematic uncertainties that are larger than the bias itself, so that the new $\widehat{\theta}'$ may not be better than the original.

(c) Efficiency is the ratio of the minimum possible variance for any estimator of θ to the variance $V[\widehat{\theta}]$ of the estimator actually used. Under rather general conditions, the minimum variance is given by the Rao-Cramér-Frechet bound,

$$\sigma_{\min}^2 = \left(1 + \frac{\partial b}{\partial \theta}\right)^2 / I(\theta) , \qquad (36.1)$$

where

$$I(\theta) = E \left[\left(\frac{\partial}{\partial \theta} \sum_{i} \ln f(x_i; \theta) \right)^2 \right]$$
 (36.2)

is the *Fisher information*. The sum is over all data, assumed independent, and distributed according to the p.d.f. $f(x;\theta)$, b is the bias, if any, and the allowed range of x must not depend on θ .

The mean-squared error,

$$MSE = E[(\widehat{\theta} - \theta)^2] = V[\widehat{\theta}] + b^2, \qquad (36.3)$$

is a measure of an estimator's quality which combines bias and

(d) Robustness is the property of being insensitive to departures from assumptions in the p.d.f., e.g., owing to uncertainties in the distribution's tails.

Simultaneously optimizing for all the measures of estimator quality described above can lead to conflicting requirements. For example, there is in general a trade-off between bias and variance. For some common estimators, the properties above are known exactly. More generally, it is possible to evaluate them by Monte Carlo simulation. Note that they will often depend on the unknown θ .

36.1.1. Estimators for mean, variance and median:

Suppose we have a set of N independent measurements, x_i , assumed to be unbiased measurements of the same unknown quantity μ with a common, but unknown, variance σ^2 . Then

$$\hat{\mu} = \frac{1}{N} \sum_{i=1}^{N} x_i \tag{36.4}$$

$$\widehat{\sigma^2} = \frac{1}{N-1} \sum_{i=1}^{N} (x_i - \widehat{\mu})^2$$
 (36.5)

are unbiased estimators of μ and σ^2 . The variance of $\widehat{\mu}$ is σ^2/N and the variance of $\widehat{\sigma^2}$ is

$$V\left[\widehat{\sigma^2}\right] = \frac{1}{N} \left(m_4 - \frac{N-3}{N-1} \sigma^4 \right) , \qquad (36.6)$$

where m_4 is the 4th central moment of x. For Gaussian distributed x_i , this becomes $2\sigma^4/(N-1)$ for any $N\geq 2$, and for large N, the standard deviation of $\widehat{\sigma}$ (the "error of the error") is $\sigma/\sqrt{2N}$. Again, if the x_i are Gaussian, $\widehat{\mu}$ is an efficient estimator for μ , and the estimators $\widehat{\mu}$ and $\widehat{\sigma^2}$ are uncorrelated. Otherwise the arithmetic mean (36.4) is not necessarily the most efficient estimator; this is discussed further in Sec. 8.7 of Ref. 4.

If σ^2 is known, it does not improve the estimate $\widehat{\mu}$, as can be seen from Eq. (36.4); however, if μ is known, substitute it for $\widehat{\mu}$ in Eq. (36.5) and replace N-1 by N to obtain an estimator of σ^2 still

with zero bias but smaller variance. If the x_i have different, known variances σ_i^2 , then the weighted average

$$\hat{\mu} = \frac{1}{w} \sum_{i=1}^{N} w_i x_i \tag{36.7}$$

is an unbiased estimator for μ with a smaller variance than an unweighted average; here $w_i=1/\sigma_i^2$ and $w=\sum_i w_i$. The standard deviation of $\widehat{\mu}$ is $1/\sqrt{w}$.

As an estimator for the median $x_{\rm med}$, one can use the value $\widehat{x}_{\rm med}$ such that half the x_i are below and half above (the sample median). If the sample median lies between two observed values, it is set by convention halfway between them. If the p.d.f. of x has the form $f(x-\mu)$ and μ is both mean and median, then for large N the variance of the sample median approaches $1/[4Nf^2(0)]$, provided f(0)>0. Although estimating the median can often be more difficult computationally than the mean, the resulting estimator is generally more robust, as it is insensitive to the exact shape of the tails of a distribution.

36.1.2. The method of maximum likelihood:

Suppose we have a set of N measured quantities $\mathbf{x} = (x_1, \dots, x_N)$ described by a joint p.d.f. $f(\mathbf{x}; \boldsymbol{\theta})$, where $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$ is set of n parameters whose values are unknown. The *likelihood function* is given by the p.d.f. evaluated with the data \mathbf{x} , but viewed as a function of the parameters, i.e., $L(\boldsymbol{\theta}) = f(\mathbf{x}; \boldsymbol{\theta})$. If the measurements x_i are statistically independent and each follow the p.d.f. $f(\mathbf{x}; \boldsymbol{\theta})$, then the joint p.d.f. for \mathbf{x} factorizes and the likelihood function is

$$L(\boldsymbol{\theta}) = \prod_{i=1}^{N} f(x_i; \boldsymbol{\theta}) . \tag{36.8}$$

The method of maximum likelihood takes the estimators $\widehat{\boldsymbol{\theta}}$ to be those values of $\boldsymbol{\theta}$ that maximize $L(\boldsymbol{\theta})$.

Note that the likelihood function is not a p.d.f. for the parameters θ ; in frequentist statistics this is not defined. In Bayesian statistics, one can obtain the posterior p.d.f. for θ from the likelihood, but this requires multiplying by a prior p.d.f. (see Sec. 36.3.1).

It is usually easier to work with $\ln L$, and since both are maximized for the same parameter values $\boldsymbol{\theta}$, the maximum likelihood (ML) estimators can be found by solving the *likelihood equations*,

$$\frac{\partial \ln L}{\partial \theta_i} = 0 \; , \qquad i = 1, \dots, n \; .$$
 (36.9)

Often the solution must be found numerically. Maximum likelihood estimators are important because they are approximately unbiased and efficient for large data samples, under quite general conditions, and the method has a wide range of applicability.

In evaluating the likelihood function, it is important that any normalization factors in the p.d.f. that involve $\boldsymbol{\theta}$ be included. However, we will only be interested in the maximum of L and in ratios of L at different values of the parameters; hence any multiplicative factors that do not involve the parameters that we want to estimate may be dropped, including factors that depend on the data but not on $\boldsymbol{\theta}$.

Under a one-to-one change of parameters from $\boldsymbol{\theta}$ to $\boldsymbol{\eta}$, the ML estimators $\widehat{\boldsymbol{\theta}}$ transform to $\boldsymbol{\eta}(\widehat{\boldsymbol{\theta}})$. That is, the ML solution is invariant under change of parameter. However, other properties of ML estimators, in particular the bias, are not invariant under change of parameter.

The inverse V^{-1} of the covariance matrix $V_{ij} = \text{cov}[\widehat{\theta}_i, \widehat{\theta}_j]$ for a set of ML estimators can be estimated by using

$$(\widehat{V}^{-1})_{ij} = -\left. \frac{\partial^2 \ln L}{\partial \theta_i \partial \theta_j} \right|_{\widehat{\theta}} . \tag{36.10}$$

For finite samples, however, Eq. (36.10) can result in an underestimate of the variances. In the large sample limit (or in a linear model with Gaussian errors), L has a Gaussian form and $\ln L$ is (hyper)parabolic. In this case, it can be seen that a numerically equivalent way of

determining s-standard-deviation errors is from the contour given by the $\boldsymbol{\theta}'$ such that

$$\ln L(\theta') = \ln L_{\text{max}} - s^2/2,$$
 (36.11)

where $\ln L_{\rm max}$ is the value of $\ln L$ at the solution point (compare with Eq. (36.58)). The extreme limits of this contour on the θ_i axis give an approximate s-standard-deviation confidence interval for θ_i (see Section 36.3.2.4).

In the case where the size n of the data sample x_1,\ldots,x_n is small, the unbinned maximum likelihood method, i.e., use of equation (36.8), is preferred since binning can only result in a loss of information, and hence larger statistical errors for the parameter estimates. The sample size n can be regarded as fixed, or the analyst can choose to treat it as a Poisson-distributed variable; this latter option is sometimes called "extended maximum likelihood" (see, e.g., Refs. [6–8]) .

If the sample is large, it can be convenient to bin the values in a histogram, so that one obtains a vector of data $\mathbf{n} = (n_1, \dots, n_N)$ with expectation values $\mathbf{v} = E[\mathbf{n}]$ and probabilities $f(\mathbf{n}; \mathbf{v})$. Then one may maximize the likelihood function based on the contents of the bins (so i labels bins). This is equivalent to maximizing the likelihood ratio $\lambda(\boldsymbol{\theta}) = f(\mathbf{n}; \mathbf{v}(\boldsymbol{\theta}))/f(\mathbf{n}; \mathbf{n})$, or to minimizing the equivalent quantity $-2 \ln \lambda(\boldsymbol{\theta})$. For independent Poisson distributed n_i this is [9]

$$-2\ln\lambda(\boldsymbol{\theta}) = 2\sum_{i=1}^{N} \left[\nu_i(\boldsymbol{\theta}) - n_i + n_i \ln\frac{n_i}{\nu_i(\boldsymbol{\theta})}\right], \qquad (36.12)$$

where for bins with $n_i = 0$, the last term in (36.12) is zero. The expression (36.12) without the terms $\nu_i - n_i$ also gives $-2 \ln \lambda(\theta)$ for multinomially distributed n_i , *i.e.*, when the total number of entries is regarded as fixed. In the limit of zero bin width, maximizing (36.12) is equivalent to maximizing the unbinned likelihood function (36.8).

A benefit of binning is that it allows for a goodness-of-fit test (see Sec. 36.2.2). Assuming the model is correct, then according to Wilks' theorem, for sufficiently large ν_i and providing certain regularity conditions are met, the minimum of $-2\ln\lambda$ as defined by Eq. (36.12) follows a χ^2 distribution (see, e.g., Ref. 3). If there are N bins and m fitted parameters, then the number of degrees of freedom for the χ^2 distribution is N-m if the data are treated as Poisson-distributed, and N-m-1 if the n_i are multinomially distributed.

Suppose the n_i are Poisson-distributed and the overall normalization $\nu_{\rm tot} = \sum_i \nu_i$ is taken as an adjustable parameter, so that $\nu_i = \nu_{\rm tot} p_i(\boldsymbol{\theta})$, where the probability to be in the ith bin, $p_i(\boldsymbol{\theta})$, does not depend on $\nu_{\rm tot}$. Then by minimizing Eq. (36.12), one obtains that the area under the fitted function is equal to the sum of the histogram contents, i.e., $\sum_i \nu_i = \sum_i n_i$. This is not the case for parameter estimation methods based on a least-squares procedure with traditional weights (see, e.g., Ref. 8).

${\bf 36.1.3.} \quad \textit{The method of least squares}:$

The method of least squares (LS) coincides with the method of maximum likelihood in the following special case. Consider a set of N independent measurements y_i at known points x_i . The measurement y_i is assumed to be Gaussian distributed with mean $F(x_i; \theta)$ and known variance σ_i^2 . The goal is to construct estimators for the unknown parameters θ . The likelihood function contains the sum of squares

$$\chi^{2}(\boldsymbol{\theta}) = -2 \ln L(\boldsymbol{\theta}) + \text{ constant } = \sum_{i=1}^{N} \frac{(y_{i} - F(x_{i}; \boldsymbol{\theta}))^{2}}{\sigma_{i}^{2}}.$$
 (36.13)

The set of parameters θ which maximize L is the same as those which minimize χ^2

The minimum of Equation (36.13) defines the least-squares estimators $\hat{\boldsymbol{\theta}}$ for the more general case where the y_i are not Gaussian distributed as long as they are independent. If they are not independent but rather have a covariance matrix $V_{ij} = \text{cov}[y_i, y_j]$, then the LS estimators are determined by the minimum of

$$\chi^{2}(\boldsymbol{\theta}) = (\boldsymbol{y} - \boldsymbol{F}(\boldsymbol{\theta}))^{T} V^{-1} (\boldsymbol{y} - \boldsymbol{F}(\boldsymbol{\theta})), \qquad (36.14)$$

where $\mathbf{y} = (y_1, \dots, y_N)$ is the vector of measurements, $\mathbf{F}(\boldsymbol{\theta})$ is the corresponding vector of predicted values (understood as a column vector in (36.14)), and the superscript T denotes the transposed (*i.e.*, row) vector.

In many practical cases, one further restricts the problem to the situation where $F(x_i; \theta)$ is a linear function of the parameters, *i.e.*,

$$F(x_i; \boldsymbol{\theta}) = \sum_{j=1}^{m} \theta_j h_j(x_i) . \qquad (36.15)$$

Here the $h_j(x)$ are m linearly independent functions, e.g., $1, x, x^2, \ldots, x^{m-1}$, or Legendre polynomials. We require m < N and at least m of the x_i must be distinct.

Minimizing χ^2 in this case with m parameters reduces to solving a system of m linear equations. Defining $H_{ij} = h_j(x_i)$ and minimizing χ^2 by setting its derivatives with respect to the θ_i equal to zero gives the LS estimators,

$$\hat{\boldsymbol{\theta}} = (H^T V^{-1} H)^{-1} H^T V^{-1} \boldsymbol{y} \equiv D \boldsymbol{y} .$$
 (36.16)

The covariance matrix for the estimators $U_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]$ is given by

$$U = DVD^T = (H^TV^{-1}H)^{-1}, (36.17)$$

or equivalently, its inverse U^{-1} can be found from

$$(U^{-1})_{ij} = \frac{1}{2} \frac{\partial^2 \chi^2}{\partial \theta_i \partial \theta_j} \Big|_{\theta = \hat{\theta}} = \sum_{k,l=1}^N h_i(x_k) (V^{-1})_{kl} h_j(x_l) . \tag{36.18}$$

The LS estimators can also be found from the expression

$$\widehat{\boldsymbol{\theta}} = U\boldsymbol{g} \,, \tag{36.19}$$

where the vector g is defined by

$$g_i = \sum_{j,k=1}^{N} y_j h_i(x_k) (V^{-1})_{jk} . \tag{36.20}$$

For the case of uncorrelated y_i , for example, one can use (36.19) with

$$(U^{-1})_{ij} = \sum_{k=1}^{N} \frac{h_i(x_k)h_j(x_k)}{\sigma_k^2} , \qquad (36.21)$$

$$g_i = \sum_{k=1}^{N} \frac{y_k h_i(x_k)}{\sigma_k^2} \,. \tag{36.22}$$

Expanding $\chi^2(\boldsymbol{\theta})$ about $\widehat{\boldsymbol{\theta}}$, one finds that the contour in parameter space defined by

$$\chi^{2}(\boldsymbol{\theta}) = \chi^{2}(\widehat{\boldsymbol{\theta}}) + 1 = \chi_{\min}^{2} + 1 \tag{36.23}$$

has tangent planes located at approximately plus-or-minus-one standard deviation $\sigma_{\widehat{\theta}}$ from the LS estimates $\widehat{\pmb{\theta}}.$

In constructing the quantity $\chi^2(\theta)$, one requires the variances or, in the case of correlated measurements, the covariance matrix. Often these quantities are not known a priori and must be estimated from the data; an important example is where the measured value y_i represents a counted number of events in the bin of a histogram. If, for example, y_i represents a Poisson variable, for which the variance is equal to the mean, then one can either estimate the variance from the predicted value, $F(x_i; \boldsymbol{\theta})$, or from the observed number itself, y_i . In the first option, the variances become functions of the fitted parameters, which may lead to calculational difficulties. The second option can be undefined if y_i is zero, and in both cases for small y_i , the variance will be poorly estimated. In either case, one should constrain the normalization of the fitted curve to the correct value, i.e., one should determine the area under the fitted curve directly from the number of entries in the histogram (see Ref. 8, Section 7.4). A further alternative is to use the method of maximum likelihood; for binned data this can be done by minimizing Eq. (36.12)

As the minimum value of the χ^2 represents the level of agreement between the measurements and the fitted function, it can be used for assessing the goodness-of-fit; this is discussed further in Section 36.2.2.

36.1.4. The Bayesian approach:

In the frequentist methods discussed above, probability is associated only with data, not with the value of a parameter. This is no longer the case in Bayesian statistics, however, which we introduce in this section. Bayesian methods are considered further in Sec. 36.3.1 for interval estimation and in Sec. 36.2.3 for model selection. For general introductions to Bayesian statistics see, e.g., Refs. [20–23].

Suppose the outcome of an experiment is characterized by a vector of data \boldsymbol{x} , whose probability distribution depends on an unknown parameter (or parameters) $\boldsymbol{\theta}$ that we wish to determine. In Bayesian statistics, all knowledge about $\boldsymbol{\theta}$ is summarized by the posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, whose integral over any given region gives the degree of belief for $\boldsymbol{\theta}$ to take on values in that region, given the data \boldsymbol{x} . It is obtained by using Bayes' theorem,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \frac{L(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta})}{\int L(\boldsymbol{x}|\boldsymbol{\theta}')\pi(\boldsymbol{\theta}')\,d\boldsymbol{\theta}'},$$
 (36.24)

where $L(\boldsymbol{x}|\boldsymbol{\theta})$ is the likelihood function, *i.e.*, the joint p.d.f. for the data viewed as a function of $\boldsymbol{\theta}$, evaluated with the data actually obtained in the experiment, and $\pi(\boldsymbol{\theta})$ is the prior p.d.f. for $\boldsymbol{\theta}$. Note that the denominator in Eq. (36.24) serves to normalize the posterior p.d.f. to unity.

As it can be difficult to report the full posterior p.d.f. $p(\boldsymbol{\theta}|\boldsymbol{x})$, one would usually summarize it with statistics such as the mean (or median), and covariance matrix. In addition one may construct intervals with a given probability content, as is discussed in Sec. 36.3.1 on Bayesian interval estimation.

36.1.4.1. *Priors:*

Bayesian statistics supplies no unique rule for determining the prior $\pi(\theta)$; this reflects the experimenter's subjective degree of belief (or state of knowledge) about θ before the measurement was carried out. For the result to be of value to the broader community, whose members may not share these beliefs, it is important to carry out a sensitivity analysis, that is, to show how the result changes under a reasonable variation of the prior probabilities.

One might like to construct $\pi(\boldsymbol{\theta})$ to represent complete ignorance about the parameters by setting it equal to a constant. A problem here is that if the prior p.d.f. is flat in $\boldsymbol{\theta}$, then it is not flat for a nonlinear function of $\boldsymbol{\theta}$, and so a different parametrization of the problem would lead in general to a non-equivalent posterior p.d.f.

For the special case of a constant prior, one can see from Bayes' theorem (36.24) that the posterior is proportional to the likelihood, and therefore the mode (peak position) of the posterior is equal to the ML estimator. The posterior mode, however, will change in general upon a transformation of parameter. A summary statistic other than the mode may be used as the Bayesian estimator, such as the median, which is invariant under parameter transformation. But this will not in general coincide with the ML estimator.

The difficult and subjective nature of encoding personal knowledge into priors has led to what is called *objective Bayesian statistics*, where prior probabilities are based not on an actual degree of belief but rather derived from formal rules. These give, for example, priors which are invariant under a transformation of parameters or which result in a maximum gain in information for a given set of measurements. For an extensive review see, *e.g.*, Ref. 24.

Objective priors do not in general reflect degree of belief, but they could in some cases be taken as possible, although perhaps extreme, subjective priors. The posterior probabilities as well therefore do not necessarily reflect a degree of belief. However one may regard investigating a variety of objective priors to be an important part of the sensitivity analysis. Furthermore, use of objective priors with Bayes' theorem can be viewed as a recipe for producing estimators or intervals which have desirable frequentist properties.

An important procedure for deriving objective priors is due to Jeffreys. According to Jeffreys' rule one takes the prior as

$$\pi(\boldsymbol{\theta}) \propto \sqrt{\det(I(\boldsymbol{\theta}))}$$
, (36.25)

where

$$I_{ij}(\boldsymbol{\theta}) = -E\left[\frac{\partial^2 \ln L(\boldsymbol{x}|\boldsymbol{\theta})}{\partial \theta_i \partial \theta_j}\right] = -\int \frac{\partial^2 \ln L(\boldsymbol{x}|\boldsymbol{\theta})}{\partial \theta_i \partial \theta_j} L(\boldsymbol{x}|\boldsymbol{\theta}) d\boldsymbol{x} \quad (36.26)$$

is the Fisher information matrix. One can show that the Jeffreys prior leads to inference that is invariant under a transformation of parameters. One should note that the Jeffreys prior depends on the likelihood function, and thus contains information about the measurement model itself, which goes beyond one's degree of belief about the value of a parameter. As examples, the Jeffreys prior for the mean μ of a Gaussian distribution is a constant, and for the mean of a Poisson distribution one finds $\pi(\mu) \propto 1/\sqrt{\mu}$.

Neither the constant nor $1/\sqrt{\mu}$ priors can be normalized to unit area and are said to be *improper*. This can be allowed because the prior always appears multiplied by the likelihood function, and if the likelihood falls off sufficiently quickly then one may have a normalizable posterior density.

An important type of objective prior is the reference prior due to Bernardo and Berger [25]. To find the reference prior for a given problem one considers the Kullback-Leibler divergence $D_n[\pi,p]$ of the posterior $p(\boldsymbol{\theta}|\boldsymbol{x})$ relative to a prior $\pi(\boldsymbol{\theta})$, obtained from a set of data $\boldsymbol{x}=(x_1,\ldots,x_n)$, which are assumed to consist of n independent and identically distributed values of x:

$$D_n[\pi, p] = \int p(\boldsymbol{\theta}|\boldsymbol{x}) \ln \frac{p(\boldsymbol{\theta}|\boldsymbol{x})}{\pi(\boldsymbol{\theta})} d\boldsymbol{\theta}.$$
 (36.27)

This is effectively a measure of the gain in information provided by the data. The reference prior is chosen so that the expectation value of this information gain is maximized for the limiting case of $n \to \infty$, where the expectation is computed with respect to the marginal distribution of the data,

$$p(\mathbf{x}) = \int L(\mathbf{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta}) d\boldsymbol{\theta} . \tag{36.28}$$

For a single, continuous parameter the reference prior is usually identical to Jeffreys' prior. In the multiparameter case an iterative algorithm exists, which requires sorting the parameters by order of inferential importance. Often the result does not depend on this order, but when it does, this can be part of a robustness analysis. Further discussion and applications to particle physics problems can be found in Ref. 26.

36.1.4.2. Bayesian treatment of nuisance parameters:

Bayesian statistics provides a framework for incorporating systematic uncertainties into a result. Suppose, for example, that a model depends not only on parameters of interest θ , but on nuisance parameters ν , whose values are known with some limited accuracy. For a single nuisance parameter ν , for example, one might have a p.d.f. centered about its nominal value with a certain standard deviation σ_{ν} . Often a Gaussian p.d.f. provides a reasonable model for one's degree of belief about a nuisance parameter; in other cases, more complicated shapes may be appropriate. If, for example, the parameter represents a non-negative quantity then a log-normal or gamma p.d.f. can be a more natural choice than a Gaussian truncated at zero. The likelihood function, prior, and posterior p.d.f. sthen all depend on both θ and ν , and are related by Bayes' theorem, as usual. One can obtain the posterior p.d.f. for θ alone by integrating over the nuisance parameters, i.e.,

$$p(\boldsymbol{\theta}|\boldsymbol{x}) = \int p(\boldsymbol{\theta}, \boldsymbol{\nu}|\boldsymbol{x}) d\boldsymbol{\nu}. \tag{36.29}$$

Such integrals can often not be carried out in closed form, and if the number of nuisance parameters is large, then they can be difficult to compute with standard Monte Carlo methods. *Markov Chain Monte Carlo* (MCMC) is often used for computing integrals of this type (see Sec. 37.5).

If the prior joint p.d.f. for θ and ν factorizes, then integrating the posterior p.d.f. over ν is equivalent to replacing the likelihood function by the marginal likelihood (see Ref. 27),

$$L_{\rm m}(\boldsymbol{x}|\boldsymbol{\theta}) = \int L(\boldsymbol{x}|\boldsymbol{\theta}, \boldsymbol{\nu}) \pi(\boldsymbol{\nu}) \, d\boldsymbol{\nu} . \tag{36.30}$$

The marginal likelihood can also be used together with frequentist methods that employ the likelihood function such as ML estimation of parameters. The results then have a mixed frequentist/Bayesian character, where the systematic uncertainty due to limited knowledge of the nuisance parameters is built in (see Ref. 28). Although this may make it more difficult to disentangle statistical from systematic effects, such a hybrid approach may satisfy the objective of reporting the result in a convenient way. The marginal likelihood may be compared with the profile likelihood, which is discussed in Sec. 36.3.2.3.

36.1.5. Propagation of errors:

Consider a set of n quantities $\boldsymbol{\theta}=(\theta_1,\ldots,\theta_n)$ and a set of m functions $\boldsymbol{\eta}(\boldsymbol{\theta})=(\eta_1(\boldsymbol{\theta}),\ldots,\eta_m(\boldsymbol{\theta}))$. Suppose we have estimated $\widehat{\boldsymbol{\theta}}=(\widehat{\theta}_1,\ldots,\widehat{\theta}_n)$, using, say, maximum-likelihood or least-squares, and we also know or have estimated the covariance matrix $V_{ij}=\operatorname{cov}[\widehat{\theta}_i,\widehat{\theta}_j]$. The goal of error propagation is to determine the covariance matrix for the functions, $U_{ij}=\operatorname{cov}[\widehat{\eta}_i,\widehat{\eta}_j]$, where $\widehat{\boldsymbol{\eta}}=\boldsymbol{\eta}(\widehat{\boldsymbol{\theta}})$. In particular, the diagonal elements $U_{ii}=V[\widehat{\eta}_i]$ give the variances. The new covariance matrix can be found by expanding the functions $\boldsymbol{\eta}(\boldsymbol{\theta})$ about the estimates $\widehat{\boldsymbol{\theta}}$ to first order in a Taylor series. Using this one finds

$$U_{ij} \approx \sum_{k,l} \left. \frac{\partial \eta_i}{\partial \theta_k} \frac{\partial \eta_j}{\partial \theta_l} \right|_{\widehat{\theta}} V_{kl} . \tag{36.31}$$

This can be written in matrix notation as $U \approx AVA^T$ where the matrix of derivatives A is

$$A_{ij} = \frac{\partial \eta_i}{\partial \theta_j} \Big|_{\widehat{\theta}} , \qquad (36.32)$$

and A^T is its transpose. The approximation is exact if $\eta(\theta)$ is linear (it holds, for example, in equation (36.17)). If this is not the case, the approximation can break down if, for example, $\eta(\theta)$ is significantly nonlinear close to $\widehat{\theta}$ in a region of a size comparable to the standard deviations of $\widehat{\theta}$.

36.2. Statistical tests

In addition to estimating parameters, one often wants to assess the validity of certain statements concerning the data's underlying distribution. Frequentist hypothesis tests, described in Sec. 36.2.1, provide a rule for accepting or rejecting hypotheses depending on the outcome of a measurement. In significance tests, covered in Sec. 36.2.2, one gives the probability to obtain a level of incompatibility with a certain hypothesis that is greater than or equal to the level observed with the actual data. In the Bayesian approach, the corresponding procedure is based fundamentally on the posterior probabilities of the competing hypotheses. In Sec. 36.2.3 we describe a related construct called the Bayes factor, which can be used to quantify the degree to which the data prefer one or another hypothesis.

36.2.1. Hypothesis tests:

Consider an experiment whose outcome is characterized by a vector of data \boldsymbol{x} . A *hypothesis* is a statement about the distribution of \boldsymbol{x} . It could, for example, define completely the p.d.f. for the data (a simple hypothesis), or it could specify only the functional form of the p.d.f., with the values of one or more parameters left open (a composite hypothesis).

A statistical test is a rule that states for which values of \boldsymbol{x} a given hypothesis (often called the null hypothesis, H_0) should be rejected. This is done by defining a region of \boldsymbol{x} -space called the critical region, w, such that there is no more than a specified probability under H_0 , α , called the size or significance level of the test, to find $\boldsymbol{x} \in w$. If the data are discrete, it may not possible to find a critical region with exact probability content α , and thus we require $P(\boldsymbol{x} \in w|H_0) \leq \alpha$. If the data are observed in the critical region, H_0 is rejected.

There are in general a large (often infinite) number of regions of the data space that have probability content α and thus qualify as possible critical regions. To choose one of them one should take into account the probabilities for the data predicted by some alternative hypothesis (or set of alternatives) H_1 . Rejecting H_0 if it is true is

called a type-I error, and occurs by construction with probability no greater than α . Not rejecting H_0 if an alternative H_1 is true is called a type-II error, and for a given test this will have a certain probability β . The quantity $1-\beta$ is called the *power* of the test of H_0 with respect to the alternative H_1 . A strategy for defining the critical region can therefore be to maximize the power with respect to some alternative (or alternatives) given a fixed size α .

In high-energy physics, the components of \boldsymbol{x} might represent the measured properties of candidate events, and the critical region is defined by the cuts that one imposes in order to reject background and thus accept events likely to be of a certain desired type. Here H_0 could represent the background hypothesis and the alternative H_1 could represent the sought after signal. In other cases, H_0 could be the hypothesis that an entire event sample consists of background events only, and the alternative H_1 may represent the hypothesis of a mixture of background and signal.

Often rather than using the full set of quantities \boldsymbol{x} , it is convenient to define a test statistic, t, which can be a single number, or in any case a vector with fewer components than \boldsymbol{x} . Each hypothesis for the distribution of \boldsymbol{x} will determine a distribution for t, and the acceptance region in \boldsymbol{x} -space will correspond to a specific range of values of t.

To maximize the power of a test of H_0 with respect to the alternative H_1 , the Neyman-Pearson lemma states that the critical region w should be chosen such that for all data values x inside w, the ratio

$$\lambda(\boldsymbol{x}) = \frac{f(\boldsymbol{x}|H_1)}{f(\boldsymbol{x}|H_0)}, \qquad (36.33)$$

is greater than a given constant, the value of which is determined by the size of the test α . Here H_0 and H_1 must be simple hypotheses, i.e., they should not contain undetermined parameters.

The lemma is equivalent to the statement that (36.33) represents the optimal test statistic where the critical region is defined by a single cut on λ . This test will lead to the maximum power (e.g., probability to reject the background hypothesis if the signal hypothesis is true) for a given probability α to reject the background hypothesis if it is in fact true. It can be difficult in practice, however, to determine $\lambda(x)$, since this requires knowledge of the joint p.d.f.s $f(x|H_0)$ and $f(x|H_1)$.

In the usual case where the likelihood ratio (36.33) cannot be used explicitly, there exist a variety of other multivariate classifiers that effectively separate different types of events. Methods often used in HEP include neural networks or Fisher discriminants (see Ref. 10). Recently, further classification methods from machine-learning have been applied in HEP analyses; these include probability density estimation (PDE) techniques, kernel-based PDE (KDE or Parzen window), support vector machines, and decision trees. Techniques such as "boosting" and "bagging" can be applied to combine a number of classifiers into a stronger one with greater stability with respect to fluctuations in the training data. Descriptions of these methods can be found in [11–13], and Proceedings of the PHYSTAT conference series [14]. Software for HEP includes the TMVA [15] and StatPatternRecognition [16] packages.

36.2.2. Significance tests:

Often one wants to quantify the level of agreement between the data and a hypothesis without explicit reference to alternative hypotheses. This can be done by defining a statistic t, which is a function of the data whose value reflects in some way the level of agreement between the data and the hypothesis. The analyst must decide what values of the statistic correspond to better or worse levels of agreement with the hypothesis in question; for many goodness-of-fit statistics, there is an obvious choice.

The hypothesis in question, say, H_0 , will determine the p.d.f. $g(t|H_0)$ for the statistic. The significance of a discrepancy between the data and what one expects under the assumption of H_0 is quantified by giving the p-value, defined as the probability to find t in the region of equal or lesser compatibility with H_0 than the level of compatibility observed with the actual data. For example, if t is defined such that large values correspond to poor agreement with the hypothesis, then

the p-value would be

$$p = \int_{t_{\text{obs}}}^{\infty} g(t|H_0) dt , \qquad (36.34)$$

where t_{obs} is the value of the statistic obtained in the actual experiment.

The p-value should not be confused with the size (significance level) of a test, or the confidence level of a confidence interval (Section 36.3), both of which are pre-specified constants. We may formulate a hypothesis test, however, by defining the critical region to correspond to the data outcomes that give the lowest p-values, so that finding $p < \alpha$ implies that the data outcome was in the critical region. When constructing a p-value, one generally takes the region of data space deemed to have lower compatibility with the model being tested to have higher compatibility with a given alternative, and thus the corresponding test will have a high power with respect to this alternative.

The p-value is a function of the data, and is therefore itself a random variable. If the hypothesis used to compute the p-value is true, then for continuous data, p will be uniformly distributed between zero and one. Note that the p-value is not the probability for the hypothesis; in frequentist statistics, this is not defined. Rather, the p-value is the probability, under the assumption of a hypothesis H_0 , of obtaining data at least as incompatible with H_0 as the data actually observed.

When searching for a new phenomenon, one tries to reject the hypothesis H_0 that the data are consistent with known, e.g., Standard Model processes. If the p-value of H_0 is sufficiently low, then one is willing to accept that some alternative hypothesis is true. Often one converts the p-value into an equivalent significance Z, defined so that a Z standard deviation upward fluctuation of a Gaussian random variable would have an upper tail area equal to p, i.e.,

$$Z = \Phi^{-1}(1 - p) . \tag{36.35}$$

Here Φ is the cumulative distribution of the Standard Gaussian, and Φ^{-1} is its inverse (quantile) function. Often in HEP, the level of significance where an effect is said to qualify as a discovery is Z=5, i.e., a 5σ effect, corresponding to a p-value of 2.87×10^{-7} . One's actual degree of belief that a new process is present, however, will depend in general on other factors as well, such as the plausibility of the new signal hypothesis and the degree to which it can describe the data, one's confidence in the model that led to the observed p-value, and possible corrections for multiple observations out of which one focuses on the smallest p-value obtained (the "look-elsewhere effect"). For a review of how to incorporate systematic uncertainties into p-values see, e.g., Ref. 17; a computationally fast method that provides an approximate correction for the look-elsewhere effect is described in Ref. 18

When estimating parameters using the method of least squares, one obtains the minimum value of the quantity χ^2 (36.13). This statistic can be used to test the *goodness-of-fit*, *i.e.*, the test provides a measure of the significance of a discrepancy between the data and the hypothesized functional form used in the fit. It may also happen that no parameters are estimated from the data, but that one simply wants to compare a histogram, *e.g.*, a vector of Poisson distributed numbers $\mathbf{n}=(n_1,\ldots,n_N)$, with a hypothesis for their expectation values $\nu_i=E[n_i]$. As the distribution is Poisson with variances $\sigma_i^2=\nu_i$, the χ^2 (36.13) becomes Pearson's χ^2 statistic,

$$\chi^2 = \sum_{i=1}^{N} \frac{(n_i - \nu_i)^2}{\nu_i} \,. \tag{36.36}$$

If the hypothesis $\mathbf{\nu}=(\nu_1,\dots,\nu_N)$ is correct, and if the expected values ν_i in (36.36) are sufficiently large (or equivalently, if the measurements n_i can be treated as following a Gaussian distribution), then the χ^2 statistic will follow the χ^2 p.d.f. with the number of degrees of freedom equal to the number of measurements N minus the number of fitted parameters.

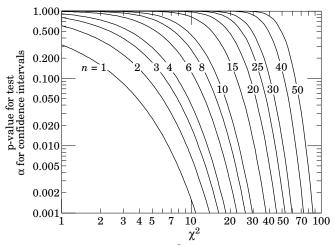

Figure 36.1: One minus the χ^2 cumulative distribution, $1 - F(\chi^2; n)$, for n degrees of freedom. This gives the p-value for the χ^2 goodness-of-fit test as well as one minus the coverage probability for confidence regions (see Sec. 36.3.2.4).

Alternatively, one may fit parameters and evaluate goodness-of-fit by minimizing $-2\ln\lambda$ from Eq. (36.12). One finds that the distribution of this statistic approaches the asymptotic limit faster than does Pearson's χ^2 , and thus computing the *p*-value with the χ^2 p.d.f. will in general be better justified (see Ref. 9 and references therein).

Assuming the goodness-of-fit statistic follows a χ^2 p.d.f., the p-value for the hypothesis is then

$$p = \int_{\chi^2}^{\infty} f(z; n_{\rm d}) dz , \qquad (36.37)$$

where $f(z; n_{\rm d})$ is the χ^2 p.d.f. and $n_{\rm d}$ is the appropriate number of degrees of freedom. Values can be obtained from Fig. 36.1 or from the ROOT function TMath::Prob. If the conditions for using the χ^2 p.d.f. do not hold, the statistic can still be defined as before, but its p.d.f. must be determined by other means in order to obtain the p-value, e.g., using a Monte Carlo calculation.

Since the mean of the χ^2 distribution is equal to $n_{\rm d}$, one expects in a "reasonable" experiment to obtain $\chi^2\approx n_{\rm d}$. Hence the quantity $\chi^2/n_{\rm d}$ is sometimes reported. Since the p.d.f. of $\chi^2/n_{\rm d}$ depends on $n_{\rm d}$, however, one must report $n_{\rm d}$ as well if one wishes to determine the p-value. The p-values obtained for different values of $\chi^2/n_{\rm d}$ are shown in Fig. 36.2.

If one finds a χ^2 value much greater than $n_{\rm d}$, and a correspondingly small p-value, one may be tempted to expect a high degree of uncertainty for any fitted parameters. Poor goodness-of-fit, however, does not mean that one will have large statistical errors for parameter estimates. If, for example, the error bars (or covariance matrix) used in constructing the χ^2 are underestimated, then this will lead to underestimated statistical errors for the fitted parameters. The standard deviations of estimators that one finds from, say, Eq. (36.11) reflect how widely the estimates would be distributed if one were to repeat the measurement many times, assuming that the hypothesis and measurement errors used in the χ^2 are also correct. They do not include the systematic error which may result from an incorrect hypothesis or incorrectly estimated measurement errors in the χ^2 .

36.2.3. Bayesian model selection :

In Bayesian statistics, all of one's knowledge about a model is contained in its posterior probability, which one obtains using Bayes' theorem (36.24). Thus one could reject a hypothesis H if its posterior probability $P(H|\mathbf{x})$ is sufficiently small. The difficulty here is that $P(H|\mathbf{x})$ is proportional to the prior probability P(H), and there will not be a consensus about the prior probabilities for the existence of new phenomena. Nevertheless one can construct a quantity called the Bayes factor (described below), which can be used to quantify the

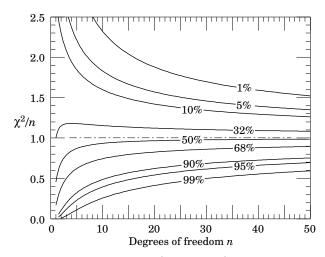

Figure 36.2: The 'reduced' χ^2 , equal to χ^2/n , for n degrees of freedom. The curves show as a function of n the χ^2/n that corresponds to a given p-value.

degree to which the data prefer one hypothesis over another, and is independent of their prior probabilities.

Consider two models (hypotheses), H_i and H_j , described by vectors of parameters $\boldsymbol{\theta}_i$ and $\boldsymbol{\theta}_j$, respectively. Some of the components will be common to both models and others may be distinct. The full prior probability for each model can be written in the form

$$\pi(H_i, \boldsymbol{\theta}_i) = P(H_i)\pi(\boldsymbol{\theta}_i|H_i) , \qquad (36.38)$$

Here $P(H_i)$ is the overall prior probability for H_i , and $\pi(\boldsymbol{\theta}_i|H_i)$ is the normalized p.d.f. of its parameters. For each model, the posterior probability is found using Bayes' theorem,

$$P(H_i|\mathbf{x}) = \frac{\int L(\mathbf{x}|\boldsymbol{\theta}_i, H_i)P(H_i)\pi(\boldsymbol{\theta}_i|H_i) d\boldsymbol{\theta}_i}{P(\mathbf{x})},$$
 (36.39)

where the integration is carried out over the internal parameters θ_i of the model. The ratio of posterior probabilities for the models is therefore

$$\frac{P(H_i|\mathbf{x})}{P(H_i|\mathbf{x})} = \frac{\int L(\mathbf{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i) d\boldsymbol{\theta}_i}{\int L(\mathbf{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i) d\boldsymbol{\theta}_i} \frac{P(H_i)}{P(H_i)}.$$
 (36.40)

The Bayes factor is defined as

$$B_{ij} = \frac{\int L(\boldsymbol{x}|\boldsymbol{\theta}_i, H_i)\pi(\boldsymbol{\theta}_i|H_i) d\boldsymbol{\theta}_i}{\int L(\boldsymbol{x}|\boldsymbol{\theta}_j, H_j)\pi(\boldsymbol{\theta}_j|H_j) d\boldsymbol{\theta}_j}.$$
 (36.41)

This gives what the ratio of posterior probabilities for models i and j would be if the overall prior probabilities for the two models were equal. If the models have no nuisance parameters i.e., no internal parameters described by priors, then the Bayes factor is simply the likelihood ratio. The Bayes factor therefore shows by how much the probability ratio of model i to model j changes in the light of the data, and thus can be viewed as a numerical measure of evidence supplied by the data in favour of one hypothesis over the other.

Although the Bayes factor is by construction independent of the overall prior probabilities $P(H_i)$ and $P(H_j)$, it does require priors for all internal parameters of a model, *i.e.*, one needs the functions $\pi(\theta_i|H_i)$ and $\pi(\theta_j|H_j)$. In a Bayesian analysis where one is only interested in the posterior p.d.f. of a parameter, it may be acceptable to take an unnormalizable function for the prior (an improper prior) as long as the product of likelihood and prior can be normalized. But improper priors are only defined up to an arbitrary multiplicative constant, and so the Bayes factor would depend on this constant. Furthermore, although the range of a constant normalized prior is unimportant for parameter determination (provided it is wider than the likelihood), this is not so for the Bayes factor when such a prior

is used for only one of the hypotheses. So to compute a Bayes factor, all internal parameters must be described by normalized priors that represent meaningful probabilities over the entire range where they are defined

An exception to this rule may be considered when the identical parameter appears in the models for both numerator and denominator of the Bayes factor. In this case one can argue that the arbitrary constants would cancel. One must exercise some caution, however, as parameters with the same name and physical meaning may still play different roles in the two models.

Both integrals in equation (36.41) are of the form

$$m = \int L(\boldsymbol{x}|\boldsymbol{\theta})\pi(\boldsymbol{\theta}) d\boldsymbol{\theta} , \qquad (36.42)$$

which is called the *marginal likelihood* (or in some fields called the *evidence*). A review of Bayes factors including a discussion of computational issues can be found in Ref. 30.

36.3. Intervals and limits

When the goal of an experiment is to determine a parameter θ , the result is usually expressed by quoting, in addition to the point estimate, some sort of interval which reflects the statistical precision of the measurement. In the simplest case, this can be given by the parameter's estimated value $\widehat{\theta}$ plus or minus an estimate of the standard deviation of $\widehat{\theta}$, $\sigma_{\widehat{\theta}}$. If, however, the p.d.f. of the estimator is not Gaussian or if there are physical boundaries on the possible values of the parameter, then one usually quotes instead an interval according to one of the procedures described below.

In reporting an interval or limit, the experimenter may wish to

- communicate as objectively as possible the result of the experiment;
- provide an interval that is constructed to cover the true value of the parameter with a specified probability;
- provide the information needed by the consumer of the result to draw conclusions about the parameter or to make a particular decision;
- draw conclusions about the parameter that incorporate stated prior beliefs.

With a sufficiently large data sample, the point estimate and standard deviation (or for the multiparameter case, the parameter estimates and covariance matrix) satisfy essentially all of these goals. For finite data samples, no single method for quoting an interval will achieve all of them.

In addition to the goals listed above, the choice of method may be influenced by practical considerations such as ease of producing an interval from the results of several measurements. Of course the experimenter is not restricted to quoting a single interval or limit; one may choose, for example, first to communicate the result with a confidence interval having certain frequentist properties, and then in addition to draw conclusions about a parameter using a judiciously chosen subjective Bayesian prior.

It is recommended, however, that there be a clear separation between these two aspects of reporting a result. In the remainder of this section, we assess the extent to which various types of intervals achieve the goals stated here.

$36.3.1. \;\; Bayesian \; intervals:$

As described in Sec. 36.1.4, a Bayesian posterior probability may be used to determine regions that will have a given probability of containing the true value of a parameter. In the single parameter case, for example, an interval (called a Bayesian or credible interval) $[\theta_{\rm lo}, \theta_{\rm up}]$ can be determined which contains a given fraction $1-\alpha$ of the posterior probability, *i.e.*,

$$1 - \alpha = \int_{\theta_{10}}^{\theta_{\text{up}}} p(\theta|\boldsymbol{x}) d\theta . \qquad (36.43)$$

Sometimes an upper or lower limit is desired, *i.e.*, θ_{lo} or θ_{up} can be set to a physical boundary or to plus or minus infinity. In other cases, one

might choose θ_{lo} and θ_{up} such that $p(\theta|\mathbf{x})$ is higher everywhere inside the interval than outside; these are called *highest posterior density* (HPD) intervals. Note that HPD intervals are not invariant under a nonlinear transformation of the parameter.

If a parameter is constrained to be non-negative, then the prior p.d.f. can simply be set to zero for negative values. An important example is the case of a Poisson variable n, which counts signal events with unknown mean s, as well as background with mean b, assumed known. For the signal mean s, one often uses the prior

$$\pi(s) = \begin{cases} 0 & s < 0 \\ 1 & s \ge 0 \end{cases}$$
 (36.44)

This prior is regarded as providing an interval whose frequentist properties can be studied, rather than as representing a degree of belief. In the absence of a clear discovery, (e.g., if n=0 or if in any case n is compatible with the expected background), one usually wishes to place an upper limit on s (see, however, Sec. 36.3.2.6 on "flip-flopping" concerning frequentist coverage). Using the likelihood function for Poisson distributed n,

$$L(n|s) = \frac{(s+b)^n}{n!} e^{-(s+b)} , \qquad (36.45)$$

along with the prior (36.44) in (36.24) gives the posterior density for s. An upper limit $s_{\rm up}$ at confidence level (or here, rather, credibility level) $1-\alpha$ can be obtained by requiring

$$1 - \alpha = \int_{-\infty}^{\sup} p(s|n)ds = \frac{\int_{-\infty}^{\sup} L(n|s) \pi(s) ds}{\int_{-\infty}^{\infty} L(n|s) \pi(s) ds},$$
 (36.46)

where the lower limit of integration is effectively zero because of the cut-off in $\pi(s)$. By relating the integrals in Eq. (36.46) to incomplete gamma functions, the equation reduces to

$$\alpha = e^{-s_{\text{up}}} \frac{\sum_{m=0}^{n} (s_{\text{up}} + b)^m / m!}{\sum_{m=0}^{n} b^m / m!} .$$
 (36.47)

This must be solved numerically for the limit $s_{\rm up}$. For the special case of b=0, the sums can be related to the quantile $F_{\chi^2}^{-1}$ of the χ^2 distribution (inverse of the cumulative distribution) to give

$$s_{\rm up} = \frac{1}{2} F_{\chi^2}^{-1} (1 - \alpha; n_{\rm d}) ,$$
 (36.48)

where the number of degrees of freedom is $n_{\rm d}=2(n+1)$. The quantile of the χ^2 distribution can be obtained using the ROOT function TMath::ChisquareQuantile. It so happens that for the case of b=0, the upper limits from Eq. (36.48) coincide numerically with the values of the frequentist upper limits discussed in Section 36.3.2.5. Values for $1-\alpha=0.9$ and 0.95 are given by the values $\nu_{\rm up}$ in Table 36.3. The frequentist properties of confidence intervals for the Poisson mean in this way are discussed in Refs. [2] and [19].

As in any Bayesian analysis, it is important to show how the result would change if one uses different prior probabilities. For example, one could consider the Jeffreys prior as described in Sec. 36.1.4. For this problem one finds the Jeffreys prior $\pi(s) \propto 1/\sqrt{s+b}$ for $s \geq 0$ and zero otherwise. As with the constant prior, one would not regard this as representing one's prior beliefs about s, both because it is improper and also as it depends on s. Rather it is used with Bayes' theorem to produce an interval whose frequentist properties can be studied.

36.3.2. Frequentist confidence intervals:

The unqualified phrase "confidence intervals" refers to frequentist intervals obtained with a procedure due to Neyman [29], described below. These are intervals (or in the multiparameter case, regions) constructed so as to include the true value of the parameter with a probability greater than or equal to a specified level, called the coverage probability. In this section, we discuss several techniques for producing intervals that have, at least approximately, this property.

36.3.2.1. The Neyman construction for confidence intervals:

Consider a p.d.f. $f(x;\theta)$ where x represents the outcome of the experiment and θ is the unknown parameter for which we want to construct a confidence interval. The variable x could (and often does) represent an estimator for θ . Using $f(x;\theta)$, we can find for a pre-specified probability $1-\alpha$, and for every value of θ , a set of values $x_1(\theta,\alpha)$ and $x_2(\theta,\alpha)$ such that

$$P(x_1 < x < x_2; \theta) = 1 - \alpha = \int_{x_1}^{x_2} f(x; \theta) dx$$
. (36.49)

This is illustrated in Fig. 36.3: a horizontal line segment $[x_1(\theta, \alpha), x_2(\theta, \alpha)]$ is drawn for representative values of θ . The union of such intervals for all values of θ , designated in the figure as $D(\alpha)$, is known as the *confidence belt*. Typically the curves $x_1(\theta, \alpha)$ and $x_2(\theta, \alpha)$ are monotonic functions of θ , which we assume for this discussion.

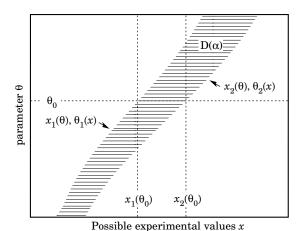

Figure 36.3: Construction of the confidence belt (see text).

Upon performing an experiment to measure x and obtaining a value x_0 , one draws a vertical line through x_0 . The confidence interval for θ is the set of all values of θ for which the corresponding line segment $[x_1(\theta, \alpha), x_2(\theta, \alpha)]$ is intercepted by this vertical line. Such confidence intervals are said to have a *confidence level* (CL) equal to $1 - \alpha$.

Now suppose that the true value of θ is θ_0 , indicated in the figure. We see from the figure that θ_0 lies between $\theta_1(x)$ and $\theta_2(x)$ if and only if x lies between $x_1(\theta_0)$ and $x_2(\theta_0)$. The two events thus have the same probability, and since this is true for any value θ_0 , we can drop the subscript 0 and obtain

$$1 - \alpha = P(x_1(\theta) < x < x_2(\theta)) = P(\theta_2(x) < \theta < \theta_1(x)). \tag{36.50}$$

In this probability statement, $\theta_1(x)$ and $\theta_2(x)$, *i.e.*, the endpoints of the interval, are the random variables and θ is an unknown constant. If the experiment were to be repeated a large number of times, the interval $[\theta_1, \theta_2]$ would vary, covering the fixed value θ in a fraction $1 - \alpha$ of the experiments.

The condition of coverage in Eq. (36.49) does not determine x_1 and x_2 uniquely, and additional criteria are needed. One possibility is to choose central intervals such that the probabilities excluded below x_1 and above x_2 are each $\alpha/2$. In other cases, one may want to report only an upper or lower limit, in which case the probability excluded below x_1 or above x_2 can be set to zero. Another principle based on likelihood ratio ordering for determining which values of x should be included in the confidence belt is discussed below.

When the observed random variable x is continuous, the coverage probability obtained with the Neyman construction is $1-\alpha$, regardless of the true value of the parameter. If x is discrete, however, it is not possible to find segments $[x_1(\theta,\alpha),x_2(\theta,\alpha)]$ that satisfy Eq. (36.49) exactly for all values of θ . By convention, one constructs the confidence belt requiring the probability $P(x_1 < x < x_2)$ to be greater than or equal to $1-\alpha$. This gives confidence intervals that include the true parameter with a probability greater than or equal to $1-\alpha$.

An equivalent method of constructing confidence intervals is to consider a test (see Sec. 36.2) of the hypothesis that the parameter's true value is θ (assume one constructs a test for all physical values of θ). One then excludes all values of θ where the hypothesis would be rejected at a significance level less than α . The remaining values constitute the confidence interval at confidence level $1-\alpha$.

In this procedure, one is still free to choose the test to be used; this corresponds to the freedom in the Neyman construction as to which values of the data are included in the confidence belt. One possibility is to use a test statistic based on the *likelihood ratio*.

$$\lambda = \frac{f(x;\theta)}{f(x;\widehat{\theta})}, \qquad (36.51)$$

where $\widehat{\theta}$ is the value of the parameter which, out of all allowed values, maximizes $f(x;\theta)$. This results in the intervals described in Ref. 31 by Feldman and Cousins. The same intervals can be obtained from the Neyman construction described above by including in the confidence belt those values of x which give the greatest values of λ .

36.3.2.2. Parameter exclusion in cases of low sensitivity:

An important example of a statistical test arises in the search for a new signal process. Suppose the parameter μ is defined such that it is proportional to the signal cross section. A statistical test may be carried out for hypothesized values of μ , which may be done by computing a p-value, p_{μ} , for each hypothesized μ . Those values not rejected in a test of size α , i.e., for which one does not find $p_{\mu} < \alpha$, constitute a confidence interval with confidence level $1-\alpha$.

In general one will find that for some regions in the parameter space of the signal model, the predictions for data are almost indistinguishable from those of the background-only model. This corresponds to the case where μ is very small, as would occur, e.g., if one searches for a Higgs boson with a mass so high that its production rate in a given experiment is negligible. That is, one has essentially no experimental sensitivity to such a model.

One would prefer that if the sensitivity to a model (or a point in a model's parameter space) is very low, then it should not be excluded. Even if the outcomes predicted with or without signal are identical, however, the probability to reject the signal model will equal α , the type-I error rate. As one often takes α to be 5%, this would mean that in a large number of searches covering a broad range of a signal model's parameter space, there would inevitably be excluded regions in which the experimental sensitivity is very small, and thus one may question whether it is justified to regard such parameter values as disfavored.

Exclusion of models to which one has little or no sensitivity occurs, for example, if the data fluctuate very low relative to the expectation of the background-only hypothesis. In this case the resulting upper limit on the predicted rate (cross section) of a signal model may be anomalously low. As a means of controlling this effect one often determines the mean or median limit under assumption of the background-only hypothesis using a simplified Monte Carlo simulation of the experiment. An upper limit found significantly below the background-only expectation may indicate a strong downward fluctuation of the data, or perhaps as well an incorrect estimate of the background rate.

The $\mathrm{CL_s}$ method aims to mitigate the problem of excluding models to which one is not sensitive by effectively penalizing the p-value of a tested parameter by an amount that increases with decreasing sensitivity [32,33]. The procedure is based on a statistic called $\mathrm{CL_s}$, which is defined as

$$CL_s = \frac{p_{\mu}}{1 - p_0}$$
, (36.52)

where p_0 is the *p*-value of the background-only hypothesis. In the usual formulation of the method, the *p*-values for μ and 0 are defined using a single test statistic, and the definition of CL_s above assumes this statistic is continuous; more details can be found in Refs. [32,33].

A point in a model's parameter space is regarded as excluded if one finds ${\rm CL_s} < \alpha$. As the denominator in Eq. (36.52) is always less than or equal to unity, the exclusion criterion based on ${\rm CL_s}$

is more stringent than the usual requirement $p_{\mu} < \alpha$. In this sense the CL_s procedure is conservative, and the coverage probability of the corresponding intervals will exceed the nominal confidence level $1-\alpha$. If the experimental sensitivity to a given value of μ is very low, then one finds that as p_{μ} decreases, so does the denominator $1-p_0$, and thus the condition CL_s < α is effectively prevented from being satisfied. In this way the exclusion of parameters in the case of low sensitivity is suppressed.

The CL_s procedure has the attractive feature that the resulting intervals coincide with those obtained from the Bayesian method in two important cases: the mean value of a Poisson or Gaussian distributed measurement with a constant prior. The CL_s intervals overcover for all values of the parameter μ , however, by an amount that depends on μ .

The problem of excluding parameter values to which one has little sensitivity is particularly acute when one wants to set a one-sided limit, e.g., an upper limit on a cross section. Here one tests a value of a rate parameter μ against the alternative of a lower rate, and therefore the critical region of the test is taken to correspond to data outcomes with a low event yield. If the number of events found in the search region fluctuates low enough, however, it can happen that all physically meaningful signal parameter values, including those to which one has very little sensitivity, are rejected by the test. Another solution to the problem, therefore, is to replace the one-sided test by one based on the likelihood ratio, where the critical region is not restricted to low rates. This is the approach followed in the Feldman-Cousins procedure described above. Further properties of Feldman-Cousins intervals are discussed below in Section 36.3.2.6.

36.3.2.3. Profile likelihood and treatment of nuisance parameters:

As mentioned in Section 36.3.1, one may have a model containing parameters that must be determined from data, but which are not of any interest in the final result (nuisance parameters). Suppose the likelihood $L(\theta, \nu)$ depends on parameters of interest θ and nuisance parameters ν . The nuisance parameters can be effectively removed from the problem by constructing the *profile likelihood*, defined by

$$L_{\mathbf{p}}(\boldsymbol{\theta}) = L(\boldsymbol{\theta}, \widehat{\widehat{\boldsymbol{\nu}}}(\boldsymbol{\theta})) ,$$
 (36.53)

where $\widehat{\widehat{\nu}}(\theta)$ is given by the ν that maximizes the likelihood for fixed θ . The profile likelihood may then be used to construct tests of intervals for the parameters of interest. This is in contrast to the marginal likelihood (36.30) used in the Bayesian approach. For example, one may construct the profile likelihood ratio,

$$\lambda_p(\boldsymbol{\theta}) = \frac{L_p(\boldsymbol{\theta})}{L(\widehat{\boldsymbol{\theta}}, \widehat{\boldsymbol{\nu}})},$$
 (36.54)

where $\hat{\boldsymbol{\theta}}$ and $\hat{\boldsymbol{\nu}}$ are the ML estimators. The ratio $\lambda_{\rm p}$ can be used in place of the likelihood ratio (36.51) for inference about $\boldsymbol{\theta}$. The resulting intervals for the parameters of interest are not guaranteed to have the exact coverage probability for all values of the nuisance parameters, but in cases of practical interest the approximation is found to be very good. Further discussion on use of the profile likelihood can be found in, e.g., Refs. [37–39] and other contributions to the PHYSTAT conferences [14].

36.3.2.4. Gaussian distributed measurements:

An important example of constructing a confidence interval is when the data consists of a single random variable x that follows a Gaussian distribution; this is often the case when x represents an estimator for a parameter and one has a sufficiently large data sample. If there is more than one parameter being estimated, the multivariate Gaussian is used. For the univariate case with known σ ,

$$1 - \alpha = \frac{1}{\sqrt{2\pi}\sigma} \int_{\mu-\delta}^{\mu+\delta} e^{-(x-\mu)^2/2\sigma^2} dx = \operatorname{erf}\left(\frac{\delta}{\sqrt{2}\sigma}\right)$$
 (36.55)

is the probability that the measured value x will fall within $\pm \delta$ of the true value μ . From the symmetry of the Gaussian with respect to x and μ , this is also the probability for the interval $x \pm \delta$ to include μ . Fig. 36.4 shows a $\delta = 1.64\sigma$ confidence interval unshaded. The choice $\delta = \sigma$ gives an interval called the *standard error* which has $1-\alpha = 68.27\%$ if σ is known. Values of α for other frequently used choices of δ are given in Table 36.1.

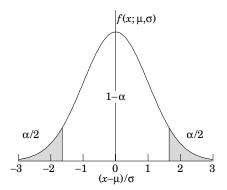

Figure 36.4: Illustration of a symmetric 90% confidence interval (unshaded) for a measurement of a single quantity with Gaussian errors. Integrated probabilities, defined by $\alpha = 0.1$, are as shown.

Table 36.1: Area of the tails α outside $\pm \delta$ from the mean of a Gaussian distribution.

| α | δ | α | δ |
|-----------------------|-----------|-----------|--------------|
| 0.3173 | 1σ | 0.2 | 1.28σ |
| 4.55×10^{-2} | 2σ | 0.1 | 1.64σ |
| 2.7×10^{-3} | 3σ | 0.05 | 1.96σ |
| 6.3×10^{-5} | 4σ | 0.01 | 2.58σ |
| 5.7×10^{-7} | 5σ | 0.001 | 3.29σ |
| 2.0×10^{-9} | 6σ | 10^{-4} | 3.89σ |

We can set a one-sided (upper or lower) limit by excluding above $x+\delta$ (or below $x-\delta$). The values of α for such limits are half the values in Table 36.1.

The relation (36.55) can be re-expressed using the cumulative distribution function for the χ^2 distribution as

$$\alpha = 1 - F(\chi^2; n) , \qquad (36.56)$$

for $\chi^2 = (\delta/\sigma)^2$ and n=1 degree of freedom. This can be obtained from Fig. 36.1 on the n=1 curve or by using the ROOT function

For multivariate measurements of, say, n parameter estimates $\widehat{\boldsymbol{\theta}}=(\widehat{\theta}_1,\ldots,\widehat{\theta}_n)$, one requires the full covariance matrix $V_{ij}=\cos[\widehat{\theta}_i,\widehat{\theta}_j]$, which can be estimated as described in Sections 36.1.2 and 36.1.3. Under fairly general conditions with the methods of maximum-likelihood or least-squares in the large sample limit, the estimators will be distributed according to a multivariate Gaussian centered about the true (unknown) values $\boldsymbol{\theta}$, and furthermore, the likelihood function itself takes on a Gaussian shape.

The standard error ellipse for the pair $(\widehat{\theta}_i, \widehat{\theta}_j)$ is shown in Fig. 36.5, corresponding to a contour $\chi^2 = \chi^2_{\min} + 1$ or $\ln L = \ln L_{\max} - 1/2$. The ellipse is centered about the estimated values $\widehat{\boldsymbol{\theta}}$, and the tangents to the ellipse give the standard deviations of the estimators, σ_i and σ_j . The angle of the major axis of the ellipse is given by

$$\tan 2\phi = \frac{2\rho_{ij}\sigma_i\sigma_j}{\sigma_j^2 - \sigma_i^2}, \qquad (36.57)$$

where $\rho_{ij} = \text{cov}[\hat{\theta}_i, \hat{\theta}_j]/\sigma_i \sigma_j$ is the correlation coefficient.

The correlation coefficient can be visualized as the fraction of the distance σ_i from the ellipse's horizontal center-line at which the ellipse becomes tangent to vertical, *i.e.*, at the distance $\rho_{ij}\sigma_i$ below the center-line as shown. As ρ_{ij} goes to +1 or -1, the ellipse thins to a diagonal line.

It could happen that one of the parameters, say, θ_j , is known from previous measurements to a precision much better than σ_j , so that the current measurement contributes almost nothing to the knowledge of θ_j . However, the current measurement of θ_i and its dependence on θ_j may still be important. In this case, instead of quoting both parameter

Table 36.2: $\Delta \chi^2$ or $2\Delta \ln L$ corresponding to a coverage probability $1-\alpha$ in the large data sample limit, for joint estimation of m parameters.

| $(1-\alpha)$ (%) | m = 1 | m = 2 | m = 3 |
|------------------|-------|-------|-------|
| 68.27 | 1.00 | 2.30 | 3.53 |
| 90. | 2.71 | 4.61 | 6.25 |
| 95. | 3.84 | 5.99 | 7.82 |
| 95.45 | 4.00 | 6.18 | 8.03 |
| 99. | 6.63 | 9.21 | 11.34 |
| 99.73 | 9.00 | 11.83 | 14.16 |

estimates and their correlation, one sometimes reports the value of θ_i , which minimizes χ^2 at a fixed value of θ_j , such as the PDG best value. This θ_i value lies along the dotted line between the points where the ellipse becomes tangent to vertical, and has statistical error σ_{inner} as shown on the figure, where $\sigma_{\text{inner}} = (1 - \rho_{ij}^2)^{1/2} \sigma_i$. Instead of the correlation ρ_{ij} , one reports the dependency $d\hat{\theta}_i/d\theta_j$ which is the slope of the dotted line. This slope is related to the correlation coefficient by $d\hat{\theta}_i/d\theta_j = \rho_{ij} \times \frac{\sigma_i}{\sigma_i}$.

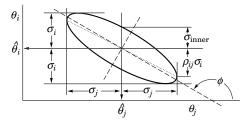

Figure 36.5: Standard error ellipse for the estimators $\hat{\theta}_i$ and $\hat{\theta}_i$. In this case the correlation is negative.

As in the single-variable case, because of the symmetry of the Gaussian function between θ and $\hat{\theta}$, one finds that contours of constant $\ln L$ or χ^2 cover the true values with a certain, fixed probability. That is, the confidence region is determined by

$$\ln L(\boldsymbol{\theta}) \ge \ln L_{\text{max}} - \Delta \ln L , \qquad (36.58)$$

or where a χ^2 has been defined for use with the method of least-squares,

$$\chi^2(\boldsymbol{\theta}) \le \chi^2_{\min} + \Delta \chi^2 \ . \tag{36.59}$$

Values of $\Delta \chi^2$ or $2\Delta \ln L$ are given in Table 36.2 for several values of the coverage probability and number of fitted parameters.

For finite non-Gaussian data samples, the probability for the regions determined by equations (36.58) or (36.59) to cover the true value of θ will depend on θ , so these are not exact confidence regions according to our previous definition. Nevertheless, they can still have a coverage probability only weakly dependent on the true parameter, and approximately as given in Table 36.2. In any case, the coverage probability of the intervals or regions obtained according to this procedure can in principle be determined as a function of the true parameter(s), for example, using a Monte Carlo calculation.

One of the practical advantages of intervals that can be constructed from the log-likelihood function or χ^2 is that it is relatively simple to produce the interval for the combination of several experiments. If N independent measurements result in log-likelihood functions $\ln L_i(\boldsymbol{\theta})$, then the combined log-likelihood function is simply the sum,

$$\ln L(\boldsymbol{\theta}) = \sum_{i=1}^{N} \ln L_i(\boldsymbol{\theta}) . \tag{36.60}$$

This can then be used to determine an approximate confidence interval or region with Eq. (36.58), just as with a single experiment.

36.3.2.5. Poisson or binomial data:

Another important class of measurements consists of counting a certain number of events, n. In this section, we will assume these are all events of the desired type, *i.e.*, there is no background. If n represents the number of events produced in a reaction with cross section σ , say, in a fixed integrated luminosity \mathcal{L} , then it follows a Poisson distribution with mean $\nu = \sigma \mathcal{L}$. If, on the other hand, one has selected a larger sample of N events and found n of them to have a particular property, then n follows a binomial distribution where the parameter p gives the probability for the event to possess the property in question. This is appropriate, e.g., for estimates of branching ratios or selection efficiencies based on a given total number of events.

For the case of Poisson distributed n, the upper and lower limits on the mean value ν can be found from the Neyman procedure to be

$$\nu_{\rm lo} = \frac{1}{2} F_{\chi^2}^{-1}(\alpha_{\rm lo}; 2n) ,$$
 (36.61a)

$$\nu_{\rm up} = \frac{1}{2} F_{\chi^2}^{-1} (1 - \alpha_{\rm up}; 2(n+1)) , \qquad (36.61b)$$

where the upper and lower limits are at confidence levels of $1-\alpha_{\rm lo}$ and $1-\alpha_{\rm up}$, respectively, and $F_{\chi^2}^{-1}$ is the quantile of the χ^2 distribution (inverse of the cumulative distribution). The quantiles $F_{\chi^2}^{-1}$ can be obtained from standard tables or from the ROOT routine TMath::ChisquareQuantile. For central confidence intervals at confidence level $1-\alpha$, set $\alpha_{\rm lo}=\alpha_{\rm up}=\alpha/2$.

Table 36.3: Lower and upper (one-sided) limits for the mean ν of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

| | $1 - \alpha = 90$ | $1 - \alpha = 95\%$ | | |
|----------------|-------------------|---------------------|--------------------|--------------------|
| \overline{n} | $ u_{ m lo}$ | $ u_{\mathrm{up}}$ | $ u_{\mathrm{lo}}$ | $ u_{\mathrm{up}}$ |
| 0 | _ | 2.30 | _ | 3.00 |
| 1 | 0.105 | 3.89 | 0.051 | 4.74 |
| 2 | 0.532 | 5.32 | 0.355 | 6.30 |
| 3 | 1.10 | 6.68 | 0.818 | 7.75 |
| 4 | 1.74 | 7.99 | 1.37 | 9.15 |
| 5 | 2.43 | 9.27 | 1.97 | 10.51 |
| 6 | 3.15 | 10.53 | 2.61 | 11.84 |
| 7 | 3.89 | 11.77 | 3.29 | 13.15 |
| 8 | 4.66 | 12.99 | 3.98 | 14.43 |
| 9 | 5.43 | 14.21 | 4.70 | 15.71 |
| 10 | 6.22 | 15.41 | 5.43 | 16.96 |

It happens that the upper limit from Eq. (36.61b) coincides numerically with the Bayesian upper limit for a Poisson parameter, using a uniform prior p.d.f. for ν . Values for confidence levels of 90% and 95% are shown in Table 36.3. For the case of binomially distributed n successes out of N trials with probability of success p, the upper and lower limits on p are found to be

$$p_{\text{lo}} = \frac{nF_F^{-1}[\alpha_{\text{lo}}; 2n, 2(N-n+1)]}{N-n+1 + nF_F^{-1}[\alpha_{\text{lo}}; 2n, 2(N-n+1)]},$$
 (36.62a)

$$p_{\rm up} = \frac{(n+1)F_F^{-1}[1 - \alpha_{\rm up}; 2(n+1), 2(N-n)]}{(N-n) + (n+1)F_F^{-1}[1 - \alpha_{\rm up}; 2(n+1), 2(N-n)]} . (36.62b)$$

Here ${\cal F}_F^{-1}$ is the quantile of the F distribution (also called the Fisher–Snedecor distribution; see Ref. 4).

36.3.2.6. Difficulties with intervals near a boundary:

A number of issues arise in the construction and interpretation of confidence intervals when the parameter can only take on values in a restricted range. An important example is where the mean of a Gaussian variable is constrained on physical grounds to be non-negative. This arises, for example, when the square of the neutrino mass is estimated from $\hat{m}^2 = \hat{E}^2 - \hat{p}^2$, where \hat{E} and \hat{p} are independent, Gaussian-distributed estimates of the energy and momentum. Although the true m^2 is constrained to be positive, random errors in \hat{E} and \hat{p} can easily lead to negative values for the estimate \hat{m}^2 .

If one uses the prescription given above for Gaussian distributed measurements, which says to construct the interval by taking the estimate plus-or-minus-one standard deviation, then this can give intervals that are partially or entirely in the unphysical region. In fact, by following strictly the Neyman construction for the central confidence interval, one finds that the interval is truncated below zero; nevertheless an extremely small or even a zero-length interval can result.

An additional important example is where the experiment consists of counting a certain number of events, n, which is assumed to be Poisson-distributed. Suppose the expectation value $E[n] = \nu$ is equal to s+b, where s and b are the means for signal and background processes, and assume further that b is a known constant. Then $\hat{s} = n - b$ is an unbiased estimator for s. Depending on true magnitudes of s and b, the estimate \hat{s} can easily fall in the negative region. Similar to the Gaussian case with the positive mean, the central confidence interval or even the interval that gives the upper limit for s may be of zero length.

An additional difficulty arises when a parameter estimate is not significantly far away from the boundary, in which case it is natural to report a one-sided confidence interval (often an upper limit). It is straightforward to force the Neyman prescription to produce only an upper limit by setting $x_2 = \infty$ in Eq. (36.49). Then x_1 is uniquely determined and the upper limit can be obtained. If, however, the data come out such that the parameter estimate is not so close to the boundary, one might wish to report a central confidence interval (i.e., an interval based on a two-sided test with equal upper and lower tail areas). As pointed out by Feldman and Cousins [31], however, if the decision to report an upper limit or two-sided interval is made by looking at the data ("flip-flopping"), then in general there will be parameter values for which the resulting intervals have a coverage probability less than $1-\alpha$.

With the confidence intervals suggested in [31], the prescription determines whether the interval is one- or two-sided in a way which preserves the coverage probability (and are thus said to be unified) and in addition they avoid the problem of null intervals. The intervals based on the Feldman-Cousins prescription are of this type. For a given choice of $1-\alpha$, if the parameter estimate is sufficiently close to the boundary, the method gives a one-sided limit. In the case of a Poisson variable in the presence of background, for example, this would occur if the number of observed events is compatible with the expected background. For parameter estimates increasingly far away from the boundary, i.e., for increasing signal significance, the interval makes a smooth transition from one- to two-sided, and far away from the boundary, one obtains a central interval.

The intervals according to this method for the mean of Poisson variable in the absence of background are given in Table 36.4. (Note that α in Ref. 31 is defined following Neyman [29] as the coverage probability; this is opposite the modern convention used here in which the coverage probability is $1-\alpha$.) The values of $1-\alpha$ given here refer to the coverage of the true parameter by the whole interval $[\nu_1, \nu_2]$. In Table 36.3 for the one-sided upper limit, however, $1-\alpha$ refers to the probability to have $\nu_{\rm up} \geq \nu$ (or $\nu_{\rm lo} \leq \nu$ for lower limits).

A potential difficulty with unified intervals arises if, for example, one constructs such an interval for a Poisson parameter s of some yet to be discovered signal process with, say, $1-\alpha=0.9$. If the true signal parameter is zero, or in any case much less than the expected background, one will usually obtain a one-sided upper limit on s. In a certain fraction of the experiments, however, a two-sided interval

Table 36.4: Unified confidence intervals $[\nu_1, \nu_2]$ for a the mean of a Poisson variable given n observed events in the absence of background, for confidence levels of 90% and 95%.

| | $1 - \alpha = 90$ | % | $1 - \alpha = 95\%$ | | |
|----------------|-------------------|---------|---------------------|---------|--|
| \overline{n} | ν_1 | ν_2 | ν_1 | ν_2 | |
| 0 | 0.00 | 2.44 | 0.00 | 3.09 | |
| 1 | 0.11 | 4.36 | 0.05 | 5.14 | |
| 2 | 0.53 | 5.91 | 0.36 | 6.72 | |
| 3 | 1.10 | 7.42 | 0.82 | 8.25 | |
| 4 | 1.47 | 8.60 | 1.37 | 9.76 | |
| 5 | 1.84 | 9.99 | 1.84 | 11.26 | |
| 6 | 2.21 | 11.47 | 2.21 | 12.75 | |
| 7 | 3.56 | 12.53 | 2.58 | 13.81 | |
| 8 | 3.96 | 13.99 | 2.94 | 15.29 | |
| 9 | 4.36 | 15.30 | 4.36 | 16.77 | |
| 10 | 5.50 | 16.50 | 4.75 | 17.82 | |

for s will result. Since, however, one typically chooses $1-\alpha$ to be only 0.9 or 0.95 when setting limits, the value s=0 may be found below the lower edge of the interval before the existence of the effect is well established. It must then be communicated carefully that in excluding s=0 from the interval, one is not necessarily claiming to have discovered the effect.

It must then be communicated carefully that in excluding s=0 at, say, 90 or 95% confidence level from the interval, one is not necessarily claiming to have discovered the effect, for which one would usually require a higher level of significance (e.g., 5 σ).

The intervals constructed according to the unified procedure in Ref. 31 for a Poisson variable n consisting of signal and background have the property that for n=0 observed events, the upper limit decreases for increasing expected background. This is counterintuitive, since it is known that if n=0 for the experiment in question, then no background was observed, and therefore one may argue that the expected background should not be relevant. The extent to which one should regard this feature as a drawback is a subject of some controversy (see, e.g., Ref. 36).

Another possibility is to construct a Bayesian interval as described in Section 36.3.1. The presence of the boundary can be incorporated simply by setting the prior density to zero in the unphysical region. More specifically, the prior may be chosen using formal rules such as the reference prior or Jeffreys prior mentioned in Sec. 36.1.4. The use of such priors is currently receiving increased attention in HEP.

In HEP a widely used prior for the mean μ of a Poisson distributed measurement has been uniform for $\mu \geq 0$. This prior does not follow from any fundamental rule nor can it be regarded as reflecting a reasonable degree of belief, since the prior probability for μ to lie between any two finite limits is zero. It is more appropriately regarded as a procedure for obtaining intervals with frequentist properties that can be investigated. The resulting upper limits have a coverage probability that depends on the true value of the Poisson parameter, and is nowhere smaller than the stated probability content. Lower limits and two-sided intervals for the Poisson mean based on flat priors undercover, however, for some values of the parameter, although to an extent that in practical cases may not be too severe [2,19]. Intervals constructed in this way have the advantage of being easy to derive; if several independent measurements are to be combined then one simply multiplies the likelihood functions (cf. Eq. (36.60)).

An additional alternative is presented by the intervals found from the likelihood function or χ^2 using the prescription of Equations (36.58) or (36.59). However, the coverage probability is not, in general, independent of the true parameter, and these intervals can for some parameter values undercover. The coverage probability can, of course, be determined with some extra effort and reported with the result. These intervals are also invariant under transformation of the

parameter; this is not true for Bayesian intervals with a conventional flat prior, because a uniform distribution in, say, θ will not be uniform if transformed to $1/\theta$. A study of the coverage of different intervals for a Poisson parameter can be found in [34]. Use of the likelihood function to determine approximate confidence intervals is discussed further in [35].

In any case, it is important to always report sufficient information so that the result can be combined with other measurements. Often this means giving an unbiased estimator and its standard deviation, even if the estimated value is in the unphysical region.

It can also be useful with a frequentist interval to calculate its subjective probability content using the posterior p.d.f. based on one or several reasonable guesses for the prior p.d.f. If it turns out to be significantly less than the stated confidence level, this warns that it would be particularly misleading to draw conclusions about the parameter's value from the interval alone.

37. MONTE CARLO TECHNIQUES

Revised September 2011 by G. Cowan (RHUL).

Monte Carlo techniques are often the only practical way to evaluate difficult integrals or to sample random variables governed by complicated probability density functions. Here we describe an assortment of methods for sampling some commonly occurring probability density functions.

37.1. Sampling the uniform distribution

Most Monte Carlo sampling or integration techniques assume a "random number generator," which generates uniform statistically independent values on the half open interval [0,1); for reviews see, e.g., [1,2].

Uniform random number generators are available in software libraries such as CERNLIB [3], CLHEP [4], and ROOT [5]. For example, in addition to a basic congruential generator TRandom (see below), ROOT provides three more sophisticated routines: TRandom1 implements the RANLUX generator [6] based on the method by Lüscher, and allows the user to select different quality levels, trading off quality with speed; TRandom2 is based on the maximally equidistributed combined Tausworthe generator by L'Ecuyer [7]; the TRandom3 generator implements the Mersenne twister algorithm of Matsumoto and Nishimura [8]. All of the algorithms produce a periodic sequence of numbers, and to obtain effectively random values, one must not use more than a small subset of a single period. The Mersenne twister algorithm has an extremely long period of $2^{19937}-1$.

The performance of the generators can be investigated with tests such as DIEHARD [9] or TestU01 [10]. Many commonly available congruential generators fail these tests and often have sequences (typically with periods less than 2^{32}), which can be easily exhausted on modern computers. A short period is a problem for the TRandom generator in ROOT, which, however, has the advantage that its state is stored in a single 32-bit word. The generators TRandom1, TRandom2, or TRandom3 have much longer periods, with TRandom3 being recommended by the ROOT authors as providing the best combination of speed and good random properties. For further information see, e.g., Ref. 11.

37.2. Inverse transform method

If the desired probability density function is f(x) on the range $-\infty < x < \infty$, its cumulative distribution function (expressing the probability that $x \leq a$) is given by Eq. (35.6). If a is chosen with probability density f(a), then the integrated probability up to point a, F(a), is itself a random variable which will occur with uniform probability density on [0,1]. Suppose u is generated according to a uniformly distributed in (0,1). If x can take on any value, and ignoring the endpoints, we can then find a unique x chosen from the p.d.f. f(x) for a given u if we set

$$u = F(x) , (37.1)$$

provided we can find an inverse of F, defined by

$$x = F^{-1}(u) . (37.2)$$

This method is shown in Fig. 37.1a. It is most convenient when one can calculate by hand the inverse function of the indefinite integral of f. This is the case for some common functions f(x) such as $\exp(x)$, $(1-x)^n$, and $1/(1+x^2)$ (Cauchy or Breit-Wigner), although it does not necessarily produce the fastest generator. Standard libraries contain software to implement this method numerically, working from functions or histograms in one or more dimensions, e.g., the UNU.RAN package [12], available in ROOT.

For a discrete distribution, F(x) will have a discontinuous jump of size $f(x_k)$ at each allowed $x_k, k = 1, 2, \cdots$. Choose u from a uniform distribution on (0,1) as before. Find x_k such that

$$F(x_{k-1}) < u \le F(x_k) \equiv \text{Prob}(x \le x_k) = \sum_{i=1}^k f(x_i);$$
 (37.3)

then x_k is the value we seek (note: $F(x_0) \equiv 0$). This algorithm is illustrated in Fig. 37.1b.

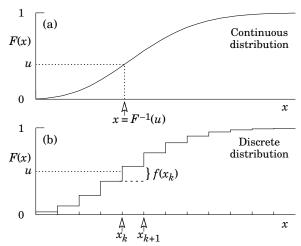

Figure 37.1: Use of a random number u chosen from a uniform distribution (0,1) to find a random number x from a distribution with cumulative distribution function F(x).

37.3. Acceptance-rejection method (Von Neumann)

Very commonly an analytic form for F(x) is unknown or too complex to work with, so that obtaining an inverse as in Eq. (37.2) is impractical. We suppose that for any given value of x, the probability density function f(x) can be computed, and further that enough is known about f(x) that we can enclose it entirely inside a shape which is C times an easily generated distribution h(x), as illustrated in Fig. 37.2. That is, $Ch(x) \geq f(x)$ must hold for all x.

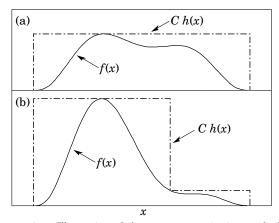

Figure 37.2: Illustration of the acceptance-rejection method. Random points are chosen inside the upper bounding figure, and rejected if the ordinate exceeds f(x). The lower figure illustrates a method to increase the efficiency (see text).

Frequently h(x) is uniform or is a normalized sum of uniform distributions. Note that both f(x) and h(x) must be normalized to unit area, and therefore, the proportionality constant C>1. To generate f(x), first generate a candidate x according to h(x). Calculate f(x) and the height of the envelope Ch(x); generate u and test if $uCh(x) \leq f(x)$. If so, accept x; if not reject x and try again. If we regard x and uCh(x) as the abscissa and ordinate of a point in a two-dimensional plot, these points will populate the entire area Ch(x) in a smooth manner; then we accept those which fall under f(x). The efficiency is the ratio of areas, which must equal 1/C; therefore we must keep C as close as possible to 1.0. Therefore, we try to choose Ch(x) to be as close to f(x) as convenience dictates, as in the lower part of Fig. 37.2.

37.4. Algorithms

Algorithms for generating random numbers belonging to many different distributions are given for example by Press [13], Ahrens and Dieter [14], Rubinstein [15], Devroye [16], Walck [17] and Gentle [18]. For many distributions, alternative algorithms exist, varying in complexity, speed, and accuracy. For time-critical applications, these algorithms may be coded in-line to remove the significant overhead often encountered in making function calls.

In the examples given below, we use the notation for the variables and parameters given in Table 35.1. Variables named "u" are assumed to be independent and uniform on [0,1). Denominators must be verified to be non-zero where relevant.

37.4.1. Exponential decay:

This is a common application of the inverse transform method, and uses the fact that if u is uniformly distributed in [0,1], then (1-u) is as well. Consider an exponential p.d.f. $f(t)=(1/\tau)\exp(-t/\tau)$ that is truncated so as to lie between two values, a and b, and renormalized to unit area. To generate decay times t according to this p.d.f., first let $\alpha=\exp(-a/\tau)$ and $\beta=\exp(-b/\tau)$; then generate u and let

$$t = -\tau \ln(\beta + u(\alpha - \beta)). \tag{37.4}$$

For $(a,b)=(0,\infty),$ we have simply $t=-\tau \ln u.$ (See also Sec. 37.4.6.)

37.4.2. Isotropic direction in 3D:

Isotropy means the density is proportional to solid angle, the differential element of which is $d\Omega = d(\cos\theta)d\phi$. Hence $\cos\theta$ is uniform $(2u_1-1)$ and ϕ is uniform $(2\pi u_2)$. For alternative generation of $\sin\phi$ and $\cos\phi$, see the next subsection.

37.4.3. Sine and cosine of random angle in 2D:

Generate u_1 and u_2 . Then $v_1=2u_1-1$ is uniform on (-1,1), and $v_2=u_2$ is uniform on (0,1). Calculate $r^2=v_1^2+v_2^2$. If $r^2>1$, start over. Otherwise, the sine (S) and cosine (C) of a random angle (i.e., uniformly distributed between zero and $2\pi)$ are given by

$$S = 2v_1v_2/r^2$$
 and $C = (v_1^2 - v_2^2)/r^2$. (37.5)

37.4.4. Gaussian distribution:

If u_1 and u_2 are uniform on (0,1), then

$$z_1 = \sin(2\pi u_1)\sqrt{-2\ln u_2}$$
 and $z_2 = \cos(2\pi u_1)\sqrt{-2\ln u_2}$ (37.6) are independent and Gaussian distributed with mean 0 and $\sigma = 1$.

There are many variants of this basic algorithm, which may be faster. For example, construct $v_1=2u_1-1$ and $v_2=2u_2-1$, which are uniform on (-1,1). Calculate $r^2=v_1^2+v_2^2$, and if $r^2>1$ start over. If $r^2<1$, it is uniform on (0,1). Then

$$z_1 = v_1 \sqrt{\frac{-2 \ln r^2}{r^2}}$$
 and $z_2 = v_2 \sqrt{\frac{-2 \ln r^2}{r^2}}$ (37.7)

are independent numbers chosen from a normal distribution with mean 0 and variance 1. $z_i' = \mu + \sigma z_i$ distributes with mean μ and variance σ^2

For a multivariate Gaussian with an $n \times n$ covariance matrix V, one can start by generating n independent Gaussian variables, $\{\eta_j\}$, with mean 0 and variance 1 as above. Then the new set $\{x_i\}$ is obtained as $x_i = \mu_i + \sum_j L_{ij}\eta_j$, where μ_i is the mean of x_i , and L_{ij} are the components of L, the unique lower triangular matrix that fulfils $V = LL^T$. The matrix L can be easily computed by the following recursive relation (Cholesky's method):

$$L_{jj} = \left(V_{jj} - \sum_{k=1}^{j-1} L_{jk}^2\right)^{1/2}, \qquad (37.8a)$$

$$L_{ij} = \frac{V_{ij} - \sum_{k=1}^{j-1} L_{ik} L_{jk}}{L_{jj}}, \ j = 1, ..., n; \ i = j+1, ..., n, (37.8b)$$

where $V_{ij} = \rho_{ij}\sigma_i\sigma_j$ are the components of V. For n=2 one has

$$L = \begin{pmatrix} \sigma_1 & 0\\ \rho \sigma_2 & \sqrt{1 - \rho^2} \sigma_2 \end{pmatrix} , \qquad (37.9)$$

and therefore the correlated Gaussian variables are generated as $x_1 = \mu_1 + \sigma_1 \eta_1$, $x_2 = \mu_2 + \rho \sigma_2 \eta_1 + \sqrt{1 - \rho^2} \sigma_2 \eta_2$.

37.4.5. $\chi^2(n)$ distribution :

To generate a variable following the χ^2 distribution for n degrees of freedom, use the Gamma distribution with k=n/2 and $\lambda=1/2$ using the method of Sec. 37.4.6.

37.4.6. Gamma distribution:

All of the following algorithms are given for $\lambda = 1$. For $\lambda \neq 1$, divide the resulting random number x by λ .

- If k=1 (the exponential distribution), accept $x=-\ln u$. (See also Sec. 37.4.1.)
- If 0 < k < 1, initialize with $v_1 = (e + k)/e$ (with e = 2.71828... being the natural log base). Generate u_1, u_2 . Define $v_2 = v_1u_1$.

Case 1: $v_2 \le 1$. Define $x = v_2^{1/k}$. If $u_2 \le e^{-x}$, accept x and stop, else restart by generating new u_1, u_2 .

Case 2: $v_2 > 1$. Define $x = -\ln([v_1 - v_2]/k)$. If $u_2 \le x^{k-1}$, accept x and stop, else restart by generating new u_1 , u_2 . Note that, for k < 1, the probability density has a pole at x = 0, so that return values of zero due to underflow must be accepted or otherwise dealt with.

• Otherwise, if k > 1, initialize with c = 3k - 0.75. Generate u_1 and compute $v_1 = u_1(1 - u_1)$ and $v_2 = (u_1 - 0.5)\sqrt{c/v_1}$. If $x = k + v_2 - 1 \le 0$, go back and generate new u_1 ; otherwise generate u_2 and compute $v_3 = 64v_1^3u_2^2$. If $v_3 \le 1 - 2v_2^2/x$ or if $\ln v_3 \le 2\{[k-1]\ln[x/(k-1)] - v_2\}$, accept x and stop; otherwise go back and generate new u_1 .

$37.4.7. \quad Binomial \ distribution:$

Begin with k=0 and generate u uniform in [0,1). Compute $P_k=(1-p)^n$ and store P_k into B. If $u\leq B$ accept $r_k=k$ and stop. Otherwise, increment k by one; compute the next P_k as $P_k\cdot (p/(1-p))\cdot (n-k)/(k+1)$; add this to B. Again, if $u\leq B$, accept $r_k=k$ and stop, otherwise iterate until a value is accepted. If p>1/2, it will be more efficient to generate r from f(r;n,q), i.e., with p and q interchanged, and then set $r_k=n-r$.

37.4.8. Poisson distribution:

Iterate until a successful choice is made: Begin with k=1 and set A=1 to start. Generate u. Replace A with uA; if now $A<\exp(-\mu)$, where μ is the Poisson parameter, accept $n_k=k-1$ and stop. Otherwise increment k by 1, generate a new u and repeat, always starting with the value of A left from the previous try.

Note that the Poisson generator used in ROOT's TRandom classes before version 5.12 (including the derived classes TRandom1, TRandom2, TRandom3) as well as the routine RNPSSN from CERNLIB, use a Gaussian approximation when μ exceeds a given threshold. This may be satisfactory (and much faster) for some applications. To do this, generate z from a Gaussian with zero mean and unit standard deviation; then use $x=\max(0,[\mu+z\sqrt{\mu}+0.5])$ where $[\]$ signifies the greatest integer \leq the expression. The routines from Numerical Recipes [13] and CLHEP's routine RandPoisson do not make this approximation (see, e.g., Ref. 11).

37.4.9. Student's t distribution:

Generate u_1 and u_2 uniform in (0,1); then $t = \sin(2\pi u_1)[n(u_2^{-2/n} - 1)]^{1/2}$ follows the Student's t distribution for n > 0 degrees of freedom (n not necessarily an integer).

Alternatively, generate x from a Gaussian with mean 0 and $\sigma^2 = 1$ according to the method of 37.4.4. Next generate y, an independent gamma random variate, according to 37.4.6 with $\lambda = 1/2$ and k = n/2. Then $z = x/\sqrt{y/n}$ is distributed as a t with n degrees of freedom.

For the special case n=1, the Breit-Wigner distribution, generate u_1 and u_2 ; set $v_1=2u_1-1$ and $v_2=2u_2-1$. If $v_1^2+v_2^2\leq 1$ accept $z=v_1/v_2$ as a Breit-Wigner distribution with unit area, center at 0.0, and FWHM 2.0. Otherwise start over. For center M_0 and FWHM Γ , use $W=z\Gamma/2+M_0$.

37.4.10. Beta distribution:

The choice of an appropriate algorithm for generation of beta distributed random numbers depends on the values of the parameters α and β . For, e.g., $\alpha=1$, one can use the transformation method to find $x=1-u^{1/\beta}$, and similarly if $\beta=1$ one has $x=u^{1/\alpha}$. For more general cases see, e.g., Refs. [17,18] and references therein.

37.5. Markov Chain Monte Carlo

In applications involving generation of random numbers following a multivariate distribution with a high number of dimensions, the transformation method may not be possible and the acceptance-rejection technique may have too low of an efficiency to be practical. If it is not required to have independent random values, but only that they follow a certain distribution, then Markov Chain Monte Carlo (MCMC) methods can be used. In depth treatments of MCMC can be found, e.g., in the texts by Robert and Casella [19], Liu [20], and the review by Neal [21].

MCMC is particularly useful in connection with Bayesian statistics, where a p.d.f. $p(\theta)$ for an n-dimensional vector of parameters $\boldsymbol{\theta} = (\theta_1, \dots, \theta_n)$ is obtained, and one needs the marginal distribution of a subset of the components. Here one samples $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta})$ and simply records the marginal distribution for the components of interest.

A simple and broadly applicable MCMC method is the Metropolis-Hastings algorithm, which allows one to generate multidimensional points $\boldsymbol{\theta}$ distributed according to a target p.d.f. that is proportional to a given function $p(\boldsymbol{\theta})$. It is not necessary to have $p(\boldsymbol{\theta})$ normalized to unit area, which is useful in Bayesian statistics, as posterior probability densities are often determined only up to an unknown normalization constant.

To generate points that follow $p(\theta)$, one first needs a proposal p.d.f. $q(\theta;\theta_0)$, which can be (almost) any p.d.f. from which independent random values θ can be generated, and which contains as a parameter another point in the same space θ_0 . For example, a multivariate Gaussian centered about θ_0 can be used. Beginning at an arbitrary starting point θ_0 , the Hastings algorithm iterates the following steps:

- 1. Generate a value θ using the proposal density $q(\theta; \theta_0)$;
- 2. Form the Hastings test ratio, $\alpha = \min \left[1, \frac{p(\boldsymbol{\theta})q(\boldsymbol{\theta}_0; \boldsymbol{\theta})}{p(\boldsymbol{\theta}_0)q(\boldsymbol{\theta}; \boldsymbol{\theta}_0)}\right]$;
- 3. Generate a value u uniformly distributed in [0, 1];
- 4. If $u \leq \alpha$, take $\theta_1 = \theta$. Otherwise, repeat the old point, *i.e.*, $\theta_1 = \theta_0$.
- 5. Set $\theta_0 = \theta_1$ and return to step 1.

If one takes the proposal density to be symmetric in θ and θ_0 , then this is the *Metropolis*-Hastings algorithm, and the test ratio becomes $\alpha = \min[1, p(\theta)/p(\theta_0)]$. That is, if the proposed θ is at a value of probability higher than θ_0 , the step is taken. If the proposed step is rejected, the old point is repeated.

Methods for assessing and optimizing the performance of the algorithm are discussed in, e.g., Refs. [19–21]. One can, for example, examine the autocorrelation as a function of the lag $k,\ i.e.$, the correlation of a sampled point with that k steps removed. This should decrease as quickly as possible for increasing k.

Generally one chooses the proposal density so as to optimize some quality measure such as the autocorrelation. For certain problems it has been shown that one achieves optimal performance when the acceptance fraction, that is, the fraction of points with $u \leq \alpha$, is around 40%. This can be adjusted by varying the width of the proposal density. For example, one can use for the proposal p.d.f. a multivariate Gaussian with the same covariance matrix as that of the target p.d.f., but scaled by a constant.

38. MONTE CARLO EVENT GENERATORS

Written January 2012 by P. Nason (INFN, Milan) and P.Z. Skands (CERN).

General-purpose Monte Carlo (GPMC) generators like HERWIG [1], HERWIG++ [2], PYTHIA 6 [3], PYTHIA 8 [4], and SHERPA [5], provide fully exclusive modeling of high-energy collisions. They play an essential role in QCD modeling (in particular for aspects beyond fixed-order perturbative QCD), in data analysis, where they are used together with detector simulation to provide a realistic estimate of the detector response to collision events, and in the planning of new experiments, where they are used to estimate signals and backgrounds in high-energy processes. They are built from several components, that describe the physics starting from very short distance scales, up to the typical scale of hadron formation and decay. Since QCD is weakly interacting at short distances (below a femtometer), the components of the GPMC dealing with short-distance physics are based upon perturbation theory. At larger distances, all soft hadronic phenomena, like hadronization and the formation of the underlying event, cannot be computed from first principles, and one must rely upon QCD-inspired models.

The purpose of this review is to illustrate the main components of these generators. It is divided into four sections. The first one deals with short-distance, perturbative phenomena. The basic concepts leading to the simulations of the dominant QCD processes are illustrated here. In the second section, hadronization phenomena are treated. The two most popular hadronization models for the formation of primary hadrons, the string and cluster models, are illustrated. The basics of the implementation of primary-hadron decays into stable ones is also illustrated here. In the third section, models for soft hadron physics are discussed. These include models for the underlying event, and for minimum-bias interactions. Issues of Bose-Einstein and color-reconnection effects are also discussed here. The fourth section briefly introduces the problem of MC tuning.

We use natural units throughout, such that c=1 and $\hbar=1$, with energy, momenta and masses measured in GeV, and time and distances measured in GeV⁻¹.

38.1. Short-distance physics in GPMC generators

The short-distance components of a GPMC generator deal with the computation of the primary process at hand, with decays of short-lived particles, and with the generation of QCD and QED radiation, on time scales below $1/\Lambda$, with Λ denoting a typical hadronic scale of a few hundred MeV, corresponding roughly to an inverse femtometer. In e^+e^- annihilation, for example, the short-distance physics describes the evolution of the system from the instant when the e^+e^- pair annihilates up to a time when the size of the produced system is just below a femtometer.

In the present discussion we take the momentum scale of the primary process to be $Q\gg \Lambda$, so that the corresponding time and distance scale 1/Q is small. Soft- and collinear-safe inclusive observables, such as total decay widths or inclusive cross sections, can be reliably computed in QCD perturbation theory (pQCD), with the perturbative expansion truncated at any fixed order n, and the remainder suppressed by $\alpha_{\rm S}(Q)^{n+1}$.

Less inclusive observables, however, can receive large enhancements that destroy the convergence of the fixed-order expansion. This is due to the presence of collinear and infrared singularities in QCD. Thus, for example, a correction in which a parton from the primary interaction splits collinearly into two partons of comparable energy, is of order $\alpha_{\rm S}(Q) \ln(Q/\Lambda)$, where the logarithm arises from an integral over a singularity regulated by the hadronic scale Λ . Since $\alpha_{\rm S}(Q) \propto 1/\ln(Q/\Lambda)$, the corresponding cross section receives a correction of order unity. Two subsequent collinear splittings yield $\alpha_{\rm S}^2(Q) \ln^2(Q/\Lambda)$, and so on. Thus, corrections of order unity arise at all orders in perturbation theory. The dominant region of phase space is the one where radiation is strongly ordered in a measure of hardness and/or angle. This means that, from a typical final-state configuration, by clustering together final-state parton pairs with, say, the smallest angle, recursively, we can reconstruct a branching tree, that may be viewed as the splitting history of the event. This history necessarily has some dependence on which measure is used to

order the clusterings. However, strong ordering in energy times angle, in virtuality or in transverse momenta are in fact equivalent in the dominant region. In fact, in the small-angle limit, the virtuality t of a parton of energy E, splitting into two on-shell partons is given by

$$t = E^2 z (1 - z)(1 - \cos \theta) \approx \frac{z(1 - z)}{2} E^2 \theta^2,$$
 (38.1)

where z and 1-z are the energy fractions carried by the produced partons, and θ is their relative angle. The transverse momentum of the final partons relative to the direction of the incoming one is given by

$$p_T^2 \approx z^2 (1-z)^2 E^2 \theta^2.$$
 (38.2)

Thus, significant differences between these measures only arise in regions with very small z or 1-z values. In QCD, because of soft divergences, these regions are in fact important, and the choice of the appropriate ordering variable is very relevant (see Sec. 38.3).

The so called KLN theorem [6,7] guarantees that large logarithmically divergent corrections, arising from final-state collinear splitting and from soft emissions, cancel against the virtual corrections in the total cross section, order by order in perturbation theory. Furthermore, the factorization theorem guarantees that initial-state collinear singularities can be factorized into the parton density functions (PDFs). Therefore, the cross section for the basic process remains accurate up to corrections of higher orders in $\alpha_{\rm S}(Q)$, provided it is interpreted as an inclusive cross section, rather than as a bare partonic cross section. Thus, for example, the leading order (LO) cross section for $e^+e^- \to q\bar{q}$ is a good LO estimate of the e^+e^- cross section for the production of a pair of quarks accompanied by an arbitrary number of collinear and soft gluons, but is not a good estimate of the cross section for the production of a $q\bar{q}$ pair with no extra radiation.

Shower algorithms are used to compute the cross section for generic hard processes including all leading-logarithmic (LL) corrections. These algorithms begin with the generation of the kinematics of the basic process, performed with a probability proportional to its LO partonic cross section, which is interpreted physically as the inclusive cross section for the basic process, followed by an arbitrary sequence of small-angle splittings. A probability is then assigned to each splitting sequence. Thus, the initial LO cross section is partitioned into the cross sections for a multitude of final states of arbitrary multiplicity. The sum of all these partial cross sections equals that of the primary process. This property of the GPMCs reflects the KLN cancellation mentioned earlier, and it is often called "unitarity of the shower process", a name that reminds us that the KLN cancellation itself is a consequence of unitarity. The fact that a quantum mechanical process can be described in terms of composition of probabilities, rather than amplitudes, follows from the LL approximation. In fact, in the dominant, strongly ordered region, subsequent splittings are separated by increasingly large times and distances, and this suppresses interference effects.

We now illustrate the basic parton-shower algorithm, as first introduced in Ref. 8. The purpose of this illustration is to give a schematic representation of how shower algorithms work, to introduce some concepts that will be referred to in the following, and to show the relationship between shower algorithms and Feynman-diagram results. For simplicity, we consider the example of e^+e^- annihilation into $q\bar{q}$ pairs. With each dominant (i.e. strongly ordered) final-state configuration one can associate a unique ordered tree diagram, by recursively clustering together final-state parton pairs with the smallest angle, and ending up with the hard production vertex (i.e. the $\gamma^* \to q\bar{q}$). The momenta of all intermediate lines of the tree diagram are then uniquely determined from the final-state momenta. Virtualities in the graph are also strongly ordered. One assigns to each splitting vertex a virtuality t, equal to the invariant mass of the pair of generated partons, the energy fractions z and 1-z of the two generated partons, and the azimuth ϕ of the splitting process with respect to the momentum of the incoming parton. For definiteness, we assume that z and ϕ are defined in the center-of-mass (CM) frame of the e^+e^- collision, although other definitions are possible that differ only beyond the LL approximation. The differential cross section for

a given final state is given by the product of the differential cross section for the initial $e^+e^-\to q\bar q$ process, multiplied by a factor

$$\Delta_{i}(t,t')\frac{\alpha_{\rm S}(t)}{2\pi}P_{i,jk}(z)\frac{dt}{t}dz\frac{d\phi}{2\pi} \tag{38.3}$$

for each intermediate line ending in a splitting vertex. We have denoted with t' the maximal virtuality that is allowed for the line, with t its virtuality, and z and ϕ refer to the splitting process. $\Delta(t,t')$ is the so-called Sudakov form factor

$$\Delta_i(t, t') = \exp\left[-\int_t^{t'} \frac{dq^2}{q^2} \frac{\alpha_S(q^2)}{2\pi} \sum_{jk} P_{i,jk}(z) dz \frac{d\phi}{2\pi}\right].$$
(38.4)

The suffixes i and jk represent the parton species of the incoming and final partons, respectively, and $P_{i,jk}(z)$ are the Altarelli-Parisi [9] splitting kernels. Final-state lines that do not undergo any further splitting are associated with a factor

$$\Delta_i(t_0, t') , \qquad (38.5)$$

where t_0 is an infrared cutoff defined by the shower hadronization scale (at which the charges are screened by hadronization) or, for an unstable particle, its width (a source cannot emit radiation with a period exceeding its lifetime).

Notice that the definition of the Sudakov form factor is such that

$$\Delta_{i}(t_{2}, t_{1}) + \int_{t_{2}}^{t_{1}} \frac{dt}{t} dz \frac{d\phi}{2\pi} \sum_{ik} \Delta_{i}(t, t_{1}) \frac{\alpha_{S}(t)}{2\pi} P_{i, jk}(z) = 1.$$
 (38.6)

This implies that the cross section for developing the shower up to a given stage does not depend on what happens next, since subsequent factors for further splitting or not splitting add up to one.

The shower cross section can then be formulated in a probabilistic way. The Sudakov form factor $\Delta_i(t_2, t_1)$ is interpreted as the probability for a splitting not to occur, for a parton of type i, starting from a branching vertex at the scale t_1 , down to a scale t_2 . Notice that $0 < \Delta_i(t_2, t_1) \le 1$, where the upper extreme is reached for $t_2 = t_1$, and the lower extreme is approached for $t_2 = t_0$. From Eq. (38.4), it seems that the Sudakov form factor should vanish if $t_2 = 0$. However, because of the presence of the running coupling in the integrand, t_2 cannot be taken smaller than some cutoff scale of the order of Λ , so that at its lower extreme the Sudakov form factor is small, but not zero. Event generation then proceeds as follows. One gets a uniform random number $0 \le r \le 1$, and seeks a solution of the equation $r = \Delta_i(t_2, t_1)$ as a function of t_2 . If r is too small and no solution exists, no splitting is generated, and the line is interpreted as a final parton. If a solution t_2 exists, a branching is generated at the scale t_2 . Its z value and the final parton species jk are generated with a probability proportional to $P_{i,jk}(z)$. The azimuth is generated uniformly. This procedure is started with both the initial quark and the antiquark, and is applied recursively to all generated partons, thus producing two shower cascades. It may generate an arbitrary number of partons, and it stops when no final-state partons undergo further splitting.

We emphasize that the shower cross section described above can be derived from perturbative QCD by keeping only the collinear-dominant real and virtual contributions to the cross section. In particular, up to terms that vanish after azimuthal averaging, the product of the cross section for the basic process, times the factors

$$\frac{\alpha_{\rm S}}{2\pi} \frac{dt}{t} dz \frac{d\phi}{2\pi} P_{i,jk}(z) \tag{38.7}$$

at each branching vertex, gives the leading collinear contribution to the tree-level cross section for the same process. The dominant virtual corrections in the same approximation are provided by the running coupling at each vertex and by the Sudakov form factors in the intermediate lines. 38.1.1. Angular correlations: In gluon splitting processes $(q \to q\bar{q}, q \to qq)$ in the collinear approximation, the distribution of the split pair is not uniform in azimuth, and the Altarelli-Parisi splitting functions are recovered only after azimuthal averaging. This dependence is due to the interference of positive and negative helicity states for the gluon that undergoes splitting. Spin correlations propagate through the splitting process, and determine acausal correlations of the EPR kind [10]. A method to partially account for these effects was introduced in Ref. 11, in which the azimuthal correlation between two successive splittings is computed by averaging over polarizations. This can then be applied at each branching step. Acausal correlations are argued to be small, and are discarded with this method, that is still used in the PYTHIA code [139]. A method that fully includes spin correlation effects was later proposed by Collins [12], and has been implemented in the fortran HERWIG code [13].

38.1.2. *Initial-state radiation*: Initial-state radiation (ISR) arises because incoming charged particles can radiate before entering the hard-scattering process. In doing so, they acquire a non-vanishing transverse momentum, and their virtuality becomes negative (spacelike). The dominant logarithmic region is the collinear one, where virtualities become larger and larger in absolute value with each emission, up to a limit given by the hardness of the basic process itself. A shower that starts by considering the highest virtualities first would thus have to work backward in time for ISR. A corresponding backwards-evolution algorithm was formulated by Sjöstrand [14], and was basically adopted in all shower models.

The key point in backwards evolution is that the evolution probability depends on the amount of partons that could have given rise to the one being evolved. This is reflected by introducing the ratio of the PDF after the branching to the PDF before the branching in the definition of the backward-evolution Sudakov form factor,

$$\Delta_i^{\text{ISR}}(t, t') = \exp\left[-\int_{t'}^t \frac{dt''}{t''} \frac{\alpha_{\text{S}}(t'')}{2\pi} \int_x^1 \frac{dz}{z} \sum_{jk} P_{j,ik}(z) \frac{f_j(t'', x/z)}{f_i(t'', x)}\right].$$
(38.8)

Notice that there are two uses of the PDFs: they are used to compute the cross section for the basic hard process, and they control ISR via backward evolution. Since the evolution is generated with leading-logarithmic accuracy, it is acceptable to use two different PDF sets for these two tasks, provided they agree at the LO level.

In the context of GPMC evolution, each ISR emission generates a finite amount of transverse momentum. Details on how the recoils generated by these transverse "kicks" are distributed among other partons in the event, in particular the ones involved in the hard process, constitute one of the main areas of difference between existing algorithms, see Ref. 15. An additional $\mathcal{O}(1\,\mathrm{GeV})$ of "primordial k_T " is typically added, to represent the sum of unresolved and/or non-perturbative motion below the shower cutoff scale.

38.1.3. Soft emissions and QCD coherence: In massless field theories like QCD, there are two sources of large logarithms of infrared origin. One has to do with collinear singularities, which arise when two final-state particles become collinear, or when a final-state particle becomes collinear to an initial-state one. The other has to do with the emission of soft gluons at arbitrary angles. Because of that, it turns out that in QCD perturbation theory two powers of large logarithms can arise for each power of $\alpha_{\rm S}$. The expansion in leading soft and collinear logarithms is often referred to as the double-logarithmic expansion.

Within the conventional parton-shower formalism, based on collinear factorization, it was shown in a sequel of publications (see Ref. 16 and references therein) that the double-logarithmic region can be correctly described by using the angle of the emissions as the ordering variable, rather than the virtuality, and that the argument of $\alpha_{\rm S}$ at the splitting vertex should be the relative parton transverse momentum after the splitting. Physically, the ordering in angle approximates the coherent interference arising from large-angle soft emission from a bunch of collinear partons. Without this effect,

the particle multiplicity would grow too rapidly with energy, in conflict with e^+e^- data. For this reason, angular ordering is used as the evolution variable in both the HERWIG [16] and HERWIG++ [17] programs, and an angular veto is imposed on the virtuality-ordered evolution in PYTHIA 6 [18].

A radical alternative formulation of QCD cascades first proposed in Ref. 19 focuses upon soft emission, rather than collinear emission, as the basic splitting mechanism. It then becomes natural to consider a branching process where it is a parton pair (i.e. a dipole) rather than a single parton, that emits a soft parton. Adding a suitable correction for non-soft, collinear partons, one can achieve in this framework the correct logarithmic structure for both soft and collinear emissions in the limit of large number of colors N_c , without any explicit angular-ordering requirement. The ARIADNE [20] and VINCIA [21] programs are based on this approach. In SHERPA, the default shower [22] is also of a dipole type [23], while the p_{\perp} -ordered showers in PYTHIA 6 and 8 represent a hybrid, combining collinear splitting kernels with dipole kinematics [24].

38.1.4. Massive quarks: Quark masses act as cut-off on collinear singularities. If the mass of a quark is below, or of the order of Λ , its effect in the shower is small. For larger quark masses, like in c or b production, it is the mass, rather than the typical hadronic scale, that cuts off collinear radiation. For a quark with energy E and mass m_Q , the divergent behavior $d\theta/\theta$ of the collinear splitting process is regulated for $\theta \leq \theta_0 = m_Q/E$. We thus expect less collinear activity for heavy quarks than for light ones, which in turn is the reason why heavy quarks carry a larger fraction of the momentum acquired in the hard production process.

This feature can be implemented with different levels of sophistication. Using the fact that soft emission exhibits a zero at zero emission angle, older parton shower algorithms simply limited the shower emission to be not smaller than the angle θ_0 . More modern approaches are used in both PYTHIA, where mass effects are included using a kind of matrix-element correction method [25], and in HERWIG++ and SHERPA, where a generalization of the Altarelli-Parisi splitting kernel is used for massive quarks [26].

38.1.5. Color information: Shower MC generators track large- N_c color information during the development of the shower. In the large- N_c limit, a quark is represented by a color line, i.e. a line with an arrow in the direction of the shower development, an antiquark by an anticolor line, with the arrow in the opposite direction, and a gluon by a pair of color-anticolor lines. The rules for color propagation are:

At the end of the shower development, partons are connected by color lines. We can have a quark directly connected by a color line to an antiquark, or via an arbitrary number of intermediate gluons, as shown in Fig. 38.1.

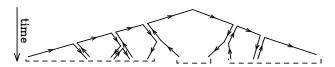

Figure 38.1: Color development of a shower in e^+e^- annihilation. Systems of color-connected partons are indicated by the dashed lines.

It is also possible for a set of gluons to be connected cyclically in color, as e.g. in the decay $\Upsilon \to ggg$.

The color information is used in angular-ordered showers, where the angle of color-connected partons determines the initial angle for the shower development, and in dipole showers, where dipoles are always color-connected partons. It is also used in hadronization models, where the initial strings or clusters used for hadronization are formed by systems of color-connected partons.

38.1.6. Electromagnetic corrections: The physics of photon emission from light charged particles can also be treated with a shower MC algorithm. A high-energy electron, for example, is accompanied by bremsstrahlung photons, which considerably affect its dynamics. Also here, similarly to the QCD case, electromagnetic corrections are of order $\alpha_{\rm em} \ln Q/m_e$, or even of order $\alpha_{\rm em} \ln Q/m_e \ln E_{\gamma}/E$ in the region where soft photon emission is important, so that their inclusion in the simulation process is mandatory. This can be done with a Monte Carlo algorithm. In case of photons emitted by leptons, at variance with the QCD case, the shower can be continued down to values of the lepton virtuality that are arbitrarily close to its mass shell. In practice, photon radiation must be cut off below a certain energy, in order for the shower algorithm to terminate. Therefore, there is always a minimum energy for emitted photons that depends upon the implementations (and so does the MC truth for a charged lepton). In the case of electrons, this energy is typically of the order of its mass. Electromagnetic radiation below this scale is not enhanced by collinear singularities, and is thus bound to be soft, so that the electron momentum is not affected by it.

For photons emitted from quarks, we have instead the obvious limitation that the photon wavelength cannot exceed the typical hadronic size. Longer-wavelength photons are in fact emitted by hadrons, rather than quarks. This last effect is in practice never modeled by existing shower MC implementations. Thus, electromagnetic radiation from quarks is cut off at a typical hadronic scale

38.1.7. Beyond-the-Standard-Model Physics: The inclusion of processes for physics beyond the Standard Model (BSM) in event generators is to some extent just a matter of implementing the relevant hard processes and (chains of) decays, with the level of difficulty depending on the complexity of the model and the degree of automation [27,28]. Notable exceptions are long-lived colored particles [29], particles in exotic color representations, and particles showering under new gauge symmetries, with a growing set of implementations documented in the individual GPMC manuals. Further complications that may be relevant are finite-width effects (discussed in Sec. 38.1.8) and the assumed threshold behavior.

In addition to code-specific implementations [15], there are a few commonly adopted standards that are useful for transferring information and events between codes. Currently, the most important of these is the Les Houches Event File (LHEF) standard [30], normally used to transfer parton-level events from a hard-process generator to a shower generator. Another important standard is the Supersymmetry Les Houches Accord (SLHA) format [31], originally used to transfer information on supersymmetric particle spectra and couplings, but by now extended to apply also to more general BSM frameworks and incorporated within the LHEF standard [32].

38.1.8. Decay Chains and Particle Widths: In most BSM processes and some SM ones, an important aspect of the event simulation is how decays of short-lived particles, such as top quarks, electroweak and Higgs bosons, and new BSM resonances, are handled. We here briefly summarize the spectrum of possibilities, but emphasize that there is no universal standard. Users are advised to check whether the treatment of a given code is adequate for the physics study at hand.

The appearance of an unstable resonance as a physical particle at some intermediate stage of the event generation implies that its production and decay processes are treated as being factorized. This is valid up to corrections of order Γ/m_0 , with Γ the width and m_0 the pole mass. States whose widths are a substantial fraction of their mass should not be treated as "physical particles," but rather as intrinsically off-shell internal propagator lines.

For states treated as physical particles, two aspects are relevant: the mass distribution of the decaying particle itself and the distributions of its decay products. For the former, matrix-element generators often use a simple δ function at m_0 . The next level up, typically used in GPMCs, is to use a Breit-Wigner distribution (relativistic or non-relativistic), which formally resums higher-order virtual corrections to the mass distribution. Note, however, that this still only generates an

improved picture for moderate fluctuations away from m_0 . Similarly to above, particles that are significantly off-shell (in units of Γ) should not be treated as resonant, but rather as internal off-shell propagator lines. In most GPMCs, further refinements are included, for instance by letting Γ be a function of m ("running widths") and by limiting the magnitude of the allowed fluctuations away from m_0 .

For the distributions of the decay products, the simplest treatment is again to assign them their respective m_0 values, with a uniform phase-space distribution. A more sophisticated treatment distributes the decay products according to the differential decay matrix elements, capturing at least the internal dynamics and helicity structure of the decay process, including EPR-like correlations. Further refinements include polarizations of the external states [33] and assigning the decay products their own Breit-Wigner distributions, the latter of which opens the possibility to include also intrinsically off-shell decay channels, like $H \to WW^*$.

During subsequent showering of the decay products, most partonshower models will preserve their total invariant mass, so as not to skew the original resonance shape.

When computing partial widths and/or modifying decay tables, one should be aware of the danger of double-counting intermediate on-shell particles, see Sec. 38.2.3.

38.1.9. *Matching with Matrix Elements*: Shower algorithms are based upon a combination of the collinear (small-angle) and soft (small-energy) approximations and are thus inaccurate for hard, large-angle emissions. They also lack next-to-leading order (NLO) corrections to the basic process.

Traditional GPMCs, like HERWIG and PYTHIA, have included for a long time the so called Matrix Element Corrections (MEC), first formulated in Ref. 34 with later developments summarized in Ref. 15. They are available for processes involving two incoming and one outgoing or one incoming and two outgoing particles, like DIS, vector boson and Higgs production and decays, and top decays. The MEC corrects the emission of the hardest jets at large angles, so that it becomes exact at leading order.

In the past decade, considerable progress has taken place in order to improve the parton shower description of hard collisions, in two different directions: the so called Matrix Elements and Parton Shower matching (ME+PS from now on), and the matching of NLO calculations and Parton Showers (NLO+PS).

The ME+PS method allows one to use tree-level matrix elements for hard, large-angle emissions. It was first formulated in the so-called CKKW paper [35], and several variants have appeared, including the CKKW-L, MLM, and pseudoshower methods, see Refs. 36, 15 for summaries. Truncated showers are required [37] in order to maintain color coherence when interfacing matrix-element calculations to angular-ordered parton showers using these methods. It is also important to ensure consistent $\alpha_{\rm S}$ choices between the real (ME-driven) and virtual (PS-driven) corrections [38].

In the ME+PS method one typically starts by generating exact matrix elements for the production of the basic process plus a certain number $\leq n$ of other partons. A minimum separation is imposed on the produced partons, requiring, for example, that the relative transverse momentum in any pair of partons is above a given cut $Q_{\rm cut}$. One then reweights these amplitudes in such a way that, in the strongly ordered region, the virtual effects that are included in the shower algorithm (i.e. running couplings and Sudakov form factors) are also accounted for. At this stage the generated configurations are tree-level accurate at large angle, and at small angle they match the results of the shower algorithm, except that there are no emissions below the scale Q_{cut} , and no final states with more than n partons. These kinematic configurations are thus fed into a GPMC, that must generate all splittings with relative transverse momentum below the scale Q_{cut} , for initial events with less than n partons, or below the scale of the smallest pair transverse momentum, for events with exactly n partons. The matching parameter Q_{cut} must be chosen to be large enough for fixed-order perturbation theory to hold, but small enough so that the shower is accurate for emissions below it. Notice that the accuracy achieved with MEC is equivalent to that of ME+PS with n=1, where MEC has the advantage of not having a matching parameter $Q_{\mathrm{cut}}.$

The popularity of the ME+PS method is due to the fact that processes with many jets appear often as background of new physics searches. These jets are typically required to be well separated, and to have large transverse momenta. These kinematical configurations, away from the small-angle region, are precisely those where GPMCs fail to be accurate, and it is thus mandatory to describe them using exact tree-level matrix element calculations.

The NLO+PS methods extend the accuracy of the generation of the basic process at the NLO level in QCD. They must thus include the radiation of an extra parton with full tree-level accuracy, since this radiation constitutes a NLO correction to the basic process. They must also include NLO virtual corrections. They can be viewed as an extension of the MEC method with the inclusion of NLO virtual corrections. They are however more general, since they are applicable to processes of arbitrary complexity. Two of these methods are now widely used: MC@NLO [39] and POWHEG [37,40], with several alternative methods now also being pursued, see Ref. 15 and references therein.

NLO+PS generators should produce NLO accurate distributions for inclusive quantities, and should generate the hardest jet with tree-level accuracy even at large angle. It should be recalled, though, that in $2 \to 1$ processes like Z/W production, GPMCs including MEC and weighted by a constant K factor may perform nearly as well, and, if suitably tuned, may even yield a better description of data. It may thus be wise to consider tuning also the NLO+PS generators for these processes.

ME+PS generators should be preferred over NLO+PS ones when one needs an accurate description of hard, large-angle emissions, beyond the hardest jet. Attempts to merge ME+PS and NLO+PS, in order to get event samples that have the advantage of both methods have appeared, see Refs. 41, 15, and references therein.

Several ME+PS implementations use existing LO generators, like ALPGEN [42], MADGRAPH [43], and others summarized in Ref. 36, for the calculation of the matrix element, and feed the partonic events to a GPMC like PYTHIA or HERWIG using the Les Houches Interface for User Processes (LHI/LHEF) [44,30]. SHERPA and HERWIG++ also include their own matrix-element generators and matching algorithms.

Several NLO+PS processes are implemented in the MC@NLO program [39], together with the new AMC@NLO development [45], and in the POWHEG BOX framework [40]. Again, SHERPA and HERWIG++, also include their own POWHEG implementation, suitably adapted with the inclusion of vetoed and truncated showers, for several processes.

38.2. Hadronization Models

In the context of event generators, hadronization denotes the process by which a set of colored partons (after showering) is transformed into a set of color-singlet primary hadrons, which may then subsequently decay further. This non-perturbative transition takes place at the $hadronization\ scale\ Q_{\rm had}$, which by construction is identical to the infrared cutoff of the parton shower. In the absence of a first-principles solution to the relevant dynamics, event generators use QCD-inspired phenomenological models to describe this transition.

A key difference between MC hadronization models and the fragmentation-function (FF) formalism used to describe inclusive hadron spectra in perturbative QCD (see Chap. 9 of PDG book) is that the former is always defined at the hadronization scale, while the latter can be defined at an arbitrary perturbative scale Q. They can therefore only be compared directly if the perturbative evolution between Q and $Q_{\rm had}$ is taken into account. FFs are calculable in pQCD, given a non-perturbative initial condition obtained by fits to hadron spectra. In the MC context, one can prove that the correct QCD evolution of the FFs arises from the shower formalism, with the hadronization model providing an explicit parametrization of the non-perturbative component. It should be kept in mind, however, that the MC modeling of shower and hadronization includes much more information on the final state since it is fully exclusive (i.e., it addresses all particles in the final state explicitly), while FFs only describe inclusive spectra. This exclusivity also enables MC models to make use of the color-flow information coming from the perturbative shower evolution (see Sec. 38.1.5) to determine between which partons the confining potentials should arise.

If one had an exact hadronization model, its dependence upon the hadronization scale $Q_{\rm had}$ would be compensated by the corresponding scale dependence of the shower algorithm, which stops generating branchings at the scale $Q_{\rm had}$. However, due to their complicated and fully exclusive nature, it is generally not possible to enforce this compensation automatically in MC models of hadronization. One must therefore be aware that the model must be "retuned" by hand if changes are made to the perturbative evolution, in particular if the infrared cutoff is modified. Tuning is discussed briefly in Sec. 38.4.

An important result in "quenched" lattice QCD (see Chap. 17 of PDG book) is that the potential of the color-dipole field between a charge and an anticharge appears to grow linearly with the separation of the charges, at distances greater than about a femtometer. This is known as "linear confinement", and it forms the starting point for the *string model of hadronization*, discussed below in Sec. 38.2.1. Alternatively, a property of perturbative QCD called "preconfinement" is the basis of the *cluster model of hadronization*, discussed in Sec. 38.2.2.

Finally, it should be emphasized that the so-called "parton level" that can be obtained by switching off hadronization in a GPMC, is not a universal concept, since each model defines the hadronization scale differently (e.g. by a cutoff in p_{\perp} , invariant mass, etc., with different tunes using different values for the cutoff). Comparisons to distributions at this level may therefore be used to provide an idea of the overall impact of hadronization corrections within a given model, but should be avoided in the context of physical observables.

38.2.1. The String Model: Starting from early concepts [46], several hadronization models based on strings have been proposed [15]. Of these, the most widely used today is the so-called Lund model [47,48], implemented in PYTHIA [139,140]. We concentrate on that particular model here, though many of the overall concepts would be shared by any string-inspired method.

Consider a color-connected quark-antiquark pair with no intermediate gluons emerging from the parton shower (like the $\bar{q}q$ pair in the center of Fig. 38.1), e.g. a red q and an antired \bar{q} . As the charges move apart, linear confinement implies that a potential $V(r)=\kappa\,r$ is reached for large distances r. (At short distances, there is a Coulomb term $\propto 1/r$ as well, but this is neglected in the Lund string.) This potential describes a string with tension $\kappa \sim 1\,\mathrm{GeV/fm} \sim 0.2\,\mathrm{GeV^2}$. The physical picture is that of a color flux tube being stretched between the q and the \bar{q} .

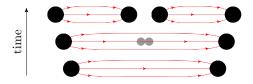

Figure 38.2: Illustration of string breaking by quark paircreation in the string field.

As the string grows, the non-perturbative creation of quark-antiquark pairs can break the string, via the process $(q\bar{q}) \rightarrow (q\bar{q}') + (q'\bar{q})$, illustrated in Fig. 38.2. More complicated color-connected quark-antiquark configurations involving intermediate gluons (like the $\bar{q}gggq$ and $\bar{q}gq$ systems on the left and right part of Fig. 38.1) are treated by representing gluons as transverse "kinks." Thus soft gluons effectively build up a transverse structure in the originally one-dimensional object, with infinitely soft ones smoothly absorbed into the string. For strings with finite-energy kinks, the space-time evolution is slightly more involved [48], but the main point is that there are no separate free parameters for gluon jets. Differences with respect to quark fragmentation arise simply because quarks are only connected to a single string piece, while gluons have one on either side, increasing their relative energy loss (per unit

invariant time) by a factor of 2, similar to the ratio of color Casimirs $C_A/C_F=2.25.$

Since the string breaks are causally disconnected (as can be realized from space-time diagrams [48]), they do not have to be considered in any specific time-ordered sequence. In the Lund model, the string breaks are generated starting with the leading ("outermost") hadrons, containing the endpoint quarks, and iterating inwards towards the center of the string, alternating randomly between the left and right sides. One can thereby split off a single on-shell hadron in each step, making it straightforward to ensure that only states consistent with known hadron states are produced.

For each breakup vertex, quantum mechanical tunneling is assumed to control the masses and p_{\perp} kicks that can be produced, leading to a Gaussian suppression

$$\operatorname{Prob}(m_q^2, p_{\perp q}^2) \propto \exp\left(\frac{-\pi m_q^2}{\kappa}\right) \exp\left(\frac{-\pi p_{\perp q}^2}{\kappa}\right) ,$$
 (38.10)

where m_q is the mass of the produced quark flavor and p_\perp is the non-perturbative transverse momentum imparted to it by the breakup process (the antiquark has the same mass and opposite p_\perp), with a universal average value of $\left\langle p_{\perp q}^2 \right\rangle = \kappa/\pi \sim (250\,\mathrm{MeV})^2$. The charm and bottom masses are sufficiently heavy that they are not produced at all in the soft fragmentation. The transverse direction is defined with respect to the string axis, so the p_\perp in a frame where the string is moving will be modified by a Lorentz boost. Note that the effective amount of "non-perturbative" p_\perp , in a Monte Carlo model with a fixed shower cutoff $Q_{\rm had}$, may be larger than the purely non-perturbative κ/π above, to account for effects of additional unresolved soft-gluon radiation below $Q_{\rm had}$. In principle, the magnitude of this additional component should scale with the cutoff, but in practice it is up to the user to enforce this by retuning the relevant parameter when changing the hadronization scale.

Since quark masses are difficult to define for light quarks, the value of the strangeness suppression is determined from experimental observables, such as the K/π and K^*/ρ ratios. The partonshower evolution generates a small amount of strangeness as well, through perturbative $g \to s\bar{s}$ splittings. The optimal value for the non-perturbative 2s/(u+d) ratio should therefore exhibit a mild anticorrelation with the amount of quarks produced in the perturbative stage.

Baryon production can also be incorporated, by allowing string breaks to produce pairs of diquarks, loosely bound states of two quarks in an overall $\bar{3}$ representation. Again, since diquark masses are difficult to define, the relative rate of diquark to quark production is extracted, e.g. from the p/π ratio, and since the perturbative shower splittings do not produce diquarks, the effective value for this parameter is mildly correlated with the amount of $g \to q\bar{q}$ splittings occurring on the shower side. More advanced scenarios for baryon production have also been proposed, see Ref. 48. Within the PYTHIA framework, a fragmentation model including baryon string junctions [49] is also available.

The next step of the algorithm is the assignment of the produced quarks within hadron multiplets. Using a nonrelativistic classification of spin states, the fragmenting q may combine with the \vec{q}' from a newly created breakup to produce a meson — or baryon, if diquarks are involved — of a given valence quark spin S and angular momentum L. The lowest-lying pseudoscalar and vector meson multiplets, and spin-1/2 and -3/2 baryons, are assumed to dominate in a string framework¹, but individual rates are not predicted by the model. This is therefore the sector that contains the largest amount of free parameters.

 $^{^{1}}$ The PYTHIA implementation includes the lightest pseudoscalar and vector mesons, with the four L=1 multiplets (scalar, tensor, and 2 pseudovectors) available but disabled by default, largely because several states are poorly known and thus may result in a worse overall description when included. For baryons, the lightest spin-1/2 and -3/2 multiplets are included.

From spin counting, the ratio V/P of vectors to pseudoscalars is expected to be 3, but in practice this is only approximately true for B mesons. For lighter flavors, the difference in phase space caused by the V-P mass splittings implies a suppression of vector production. When extracting the corresponding parameters from data, it is advisable to begin with the heaviest states, since so-called feed-down from the decays of higher-lying hadron states complicates the extraction for lighter particles, see Sec. 38.2.3. For diquarks, separate parameters control the relative rates of spin-1 diquarks vs. spin-0 ones and, likewise, have to be extracted from data.

With p_{\perp}^2 and m^2 now fixed, the final step is to select the fraction, z, of the fragmenting endpoint quark's longitudinal momentum that is carried by the created hadron, an aspect for which the string model is highly predictive. The requirement that the fragmentation be independent of the sequence in which breakups are considered (causality) imposes a "left-right symmetry" on the possible form of the fragmentation function, f(z), with the solution

$$f(z) \propto \frac{1}{z} (1-z)^a \exp\left(-\frac{b(m_h^2 + p_{\perp h}^2)}{z}\right)$$
, (38.11)

which is known as the Lund symmetric fragmentation function (normalized to unit integral). The dimensionless parameter a dampens the hard tail of the fragmentation function, towards $z \to 1$, and may in principle be flavor-dependent, while b, with dimension GeV^{-2} , is a universal constant related to the string tension [48] which determines the behavior in the soft limit, $z \to 0$. Note that the explicit mass dependence in f(z) implies a harder fragmentation function for heavier hadrons (in the rest frame of the string).

As a by-product, the probability distribution in invariant time τ of $q'\bar{q}$ breakup vertices, or equivalently $\Gamma=(\kappa\tau)^2$, is also obtained, with $dP/d\Gamma \propto \Gamma^a \exp(-b\Gamma)$ implying an area law for the color flux, and the average breakup time lying along a hyperbola of constant invariant time $\tau_0 \sim 10^{-23} {\rm s}$ [48].

For massive endpoints (e.g. c and b quarks, or hypothetical hadronizing new-physics particles), which do not move along straight lightcone sections, the exponential suppression with string area leads to modifications of the form $f(z) \to f(z)/z^{bm_Q^2}$, with m_Q the mass of the heavy quark [50]. Although different forms can also be used to describe inclusive heavy-meson spectra (see Sec 19.9 of PDG book), such choices are not consistent with causality in the string framework and hence are theoretically disfavored in this context, one well-known example being the Peterson formula [51],

$$f(z) \propto \frac{1}{z} \left(1 - \frac{1}{z} - \frac{\epsilon_Q}{1 - z} \right)^{-2} ,$$
 (38.12)

with ϵ_Q a free parameter expected to scale $\propto 1/m_Q^2$.

38.2.2. The Cluster Model: The cluster hadronization model is based on preconfinement, i.e., on the observation [52,53] that the color structure of a perturbative QCD shower evolution at any scale Q_0 is such that color-singlet subsystems of partons (labeled "clusters") occur with a universal invariant mass distribution that only depends on Q_0 and on $\Lambda_{\rm QCD}$, not on the starting scale Q, for $Q\gg Q_0\gg \Lambda_{\rm QCD}$. Further, this mass distribution is power-suppressed at large masses.

Following early models based on this universality [8,54], the cluster model developed by Webber [55] has for many years been a hallmark of the HERWIG and HERWIG++ generators, with an alternative implementation [56] now available in the SHERPA generator. The key idea, in addition to preconfinement, is to force "by hand" all gluons to split into quark-antiquark pairs at the end of the parton shower. Compared with the string description, this effectively amounts to viewing gluons as "seeds" for string breaks, rather than as kinks in a continuous object. After the splittings, a new set of low-mass color-singlet clusters is obtained, formed only by quark-antiquark pairs. These can be decayed to on-shell hadrons in a simple manner.

The algorithm starts by generating the forced $g \to q\bar{q}$ breakups, and by assigning flavors and momenta to the produced quark pairs. For a typical shower cutoff corresponding to a gluon virtuality

of $Q_{\rm had} \sim 1\,{\rm GeV}$, the p_{\perp} generated by the splittings can be neglected. The constituent light-quark masses, $m_{u,d} \sim 300\,{\rm MeV}$ and $m_s \sim 450\,{\rm MeV}$, imply a suppression (typically even an absence) of strangeness production. In principle, the model also allows for diquarks to be produced at this stage, but due to the larger constituent masses this would only become relevant for shower cutoffs larger than $1\,{\rm GeV}$

If a cluster formed in this way has an invariant mass above some cutoff value, typically 3–4 GeV, it is forced to undergo sequential $1 \rightarrow 2$ cluster breakups, along an axis defined by the constituent partons of the original cluster, until all sub-cluster masses fall below the cutoff value. Due to the preservation of the original axis in these breakups, this treatment has some resemblance to the string-like picture.

Next, on the low-mass side of the spectrum, some clusters are allowed to decay directly to a single hadron, with nearby clusters absorbing any excess momentum. This improves the description of the high-z part of the fragmentation spectrum — where the hadron carries almost all the momentum of its parent jet — at the cost of introducing one additional parameter, controlling the probability for single-hadron cluster decay.

Having obtained a final distribution of small-mass clusters, now with a strict cutoff at 3-4 GeV and with the component destined to decay to single hadrons already removed, the remaining clusters are interpreted as a smoothed-out spectrum of excited mesons, each of which decays isotropically to two hadrons, with relative probabilities proportional to the available phase space for each possible two-hadron combination that is consistent with the cluster's internal flavors, including spin degeneracy. It is important that all the light members (containing only uds) of each hadron multiplet be included, as the absence of members can lead to unphysical isospin or SU(3) flavor violation. Typically, the lightest pseudoscalar, vector, scalar, even and odd charge conjugation pseudovector, and tensor multiplets of light mesons are included. In addition, some excited vector multiplets of light mesons may be available. For baryons, usually only the lightest octet, decuplet and singlet baryons are present, although both the HERWIG++ and SHERPA implementations now include some heavier baryon multiplets as well.

Contrary to the case in the string model, the mechanism of phase-space suppression employed here leads to a natural enhancement of the lighter pseudoscalars, and no parameters beyond the spectrum of hadron masses need to be introduced at this point. The phase space also limits the transverse momenta of the produced hadrons relative to the jet axis.

Note that, since the masses and decays of excited heavy-flavor hadrons in particular are not well known, there is some freedom in the model to adjust these, which in turn will affect their relative phase-space populations.

38.2.3. Hadron and τ Decays: Of the so-called primary hadrons, originating directly from string breaks and/or cluster decays (see above), many are unstable and so decay further, until a set of particles is obtained that can be considered stable on time scales relevant to the given measurement². The decay modeling can therefore have a significant impact on final particle yields and spectra, especially for the lowest-lying hadronic states, which receive the largest relative contributions from decays (feed-down). Note that the interplay between primary production and feed-down implies that the hadronization parameters should be retuned if significant changes to the decay treatment are made.

Particle summary tables, such as those given elsewhere in this *Review*, represent a condensed summary of the available experimental measurements and hence may be incomplete and/or exhibit inconsistencies within the experimental precision. In an MC decay package, on the other hand, all information must be quantified and consistent, with all branching ratios summing to unity.

² E.g., a typical hadron-collider definition of a "stable particle" is $c\tau \geq 10 \text{ mm}$, which includes the weakly-decaying strange hadrons $(K, \Lambda, \Sigma^{\pm}, \bar{\Sigma}^{\pm}, \Xi, \Omega)$.

When adapting particle summary information for use in a decay package, a number of choices must therefore be made. The amount of ambiguity increases as more excited hadron multiplets are added to the simulation, about which less and less is known from experiment, with each GPMC making its own choices.

A related choice is how to distribute the decay products differentially in phase space, in particular which matrix elements to use. Historically, MC generators contained matrix elements only for selected (generator-specific) classes of hadron and τ decays, coupled with a Breit-Wigner smearing of the masses, truncated at the edges of the physical decay phase space (the treatment of decay thresholds can be important for certain modes [15]) . A more sophisticated treatment can then be obtained by reweighting the generated events using the obtained particle four-momenta and/or by using specialized external packages such as EVTGEN [57] for hadron decays and TAUOLA [58] for τ decays.

More recently, HERWIG++ and SHERPA include helicity-dependence in τ decays [59,60], with a more limited treatment available in PYTHIA 8 [140]. The HERWIG++ and SHERPA generators have also included significantly improved internal simulations of hadronic decays, which include spin correlations between those decays for which matrix elements are used.

HERWIG++ and PYTHIA include the probability for B mesons to oscillate into \bar{B} ones before decay. SHERPA and EVTGEN also include CP-violating effects and, for common decay modes of the neutral meson and its antiparticle, the interference between the direct decay and oscillation followed by decay.

We end on a note of warning on double counting. This may occur if a particle can decay via an intermediate on-shell resonance. An example is $a_1 \to \pi\pi\pi$ which may proceed via $a_1 \to \rho\pi$, $\rho \to \pi\pi$. If these decay channels of the a_1 are both included, each with their full partial width, a double counting of the on-shell $a_1 \to \rho\pi$ contribution would result. Such cases are normally dealt with consistently in the default MC generator packages, so this warning is mostly relevant for users that wish to edit decay tables on their own.

38.3. Models for Soft Hadron-Hadron Physics

38.3.1. Minimum-Bias and Diffraction: The term "minimum bias" (MB) originates from the experimental requirement of a minimal number of tracks (or hits) in a given instrumented region. In order to make MC predictions for such observables, all possible contributions to the relevant phase-space region must be accounted for. There are essentially four types of physics processes, which together make up the total hadron-hadron (hh) cross section: 1) elastic scattering³: $hh \to hh$, 2) single diffractive dissociation: $hh \to h + \text{gap} + X$, with X denoting anything that is not the original beam particle, and "gap" denoting a rapidity region devoid of observed activity; 3) double diffractive dissociation: $hh \to X + \text{gap} + X$, and 4) inelastic non-diffractive scattering: everything else. A fifth class may also be defined, called central diffraction $(hh \rightarrow h + \text{gap} + X + \text{gap} + h)$. Some differences exist between theoretical and experimental terminology [61]. In the experimental setting, diffraction is defined by an observable gap, of some minimal size in rapidity. In the MC context, each diffractive physics process typically produces a whole spectrum of gaps, with small ones suppressed but not excluded.

The inelastic non-diffractive part of the cross section is typically modeled either by smoothly regulating and extending the perturbative QCD scattering cross sections all the way to zero p_{\perp} [62] (PYTHIA 6, PYTHIA 8, and SHERPA), or by regulating the QCD cross sections with a sharp cutoff [63](HERWIG+JIMMY) and adding a separate class of intrinsically soft scatterings below that scale [64](HERWIG++). See also Sec. 38.3.2. In all cases, the three most important ingredients are: 1) the IR regularization of the perturbative scattering cross sections, including their PDF dependence, 2) the assumed matter distribution of the colliding hadrons, possibly including multi-parton correlations [49] and/or x dependence [65], and 3) additional soft-QCD effects

such as color reconnections and/or other collective effects, discussed in Sec. 38.3.3.

Currently, there are essentially three methods for simulating diffraction in the main MC models: 1) in PYTHIA 6, one picks a diffractive mass according to parametrized cross sections \propto dM^2/M^2 [66]. This mass is represented as a string, which is fragmented as described in Sec. 38.2.1, though differences in the effective scale of the hadronization may necessitate a (re)tuning of the fragmentation parameters for diffraction; 2) in PYTHIA 8, the high-mass tail beyond $M \sim 10\,\mathrm{GeV}$ is augmented by a partonic description in terms of pomeron PDFs [67], allowing diffractive jet production including showers and underlying event [68]; 3) the PHOJET and DPMJET programs also include central diffraction and rely directly on a formulation in terms of pomerons (color-singlet multi-gluon states) [69–71]. Cut pomerons correspond to exchanges of soft gluons while uncut ones give elastic and diffractive topologies as well as virtual corrections that help preserve unitarity. So-called "hard pomerons" provide a transition to the perturbative regime. Fragmentation is still handled using the Lund string model, so there is some overlap with the above models at the hadronization stage. In addition, a pomeron-based package exists for HERWIG [72], and an effort is underway to construct an MC implementation of the "KMR" model [73] within the SHERPA generator. Color reconnections (Sec. 38.3.3) may also play a role in creating rapidity gaps and the underlying event (Sec. 38.3.2) in destroying them.

38.3.2. Underlying Event and Jet Pedestals: In the event-generator context, the term underlying event (UE) denotes any additional activity beyond the basic process and its associated ISR and FSR activity. The dominant contribution to this is believed to come from additional color exchanges between the beam particles, which can be represented either as multiple parton-parton interactions (MPI) or as so-called cut pomerons (Sec. 38.3.1). The experimentally observed fact that the UE is more active than MB events at the same CM energy is called the "jet pedestal" effect.

The most easily identifiable consequence of MPI is arguably the possibility of observing several hard parton-parton interactions in one and the same hadron-hadron event. This tends to produce largely uncorrelated back-to-back jet pairs, with each pair having a small value of sum(\vec{p}_{\perp}). For comparison, jets from bremsstrahlung tend to be aligned with the direction of their parent initial- or final-state partons. The fraction of MPI that give rise to additional reconstructible jets is, however, quite small. Soft interactions that do not give rise to observable jets are much more plentiful, and can give significant corrections to the color flow and total scattered energy of the event. This affects the final-state activity in a more global way, increasing multiplicity and summed E_T distributions, and contributing to the break-up of the beam remnants in the forward direction.

The first detailed Monte Carlo model for perturbative MPI was proposed in Ref. 62, and with some variation this still forms the basis for most modern implementations. Some useful additional references can be found in Ref. 15. The first crucial observation is that the t-channel propagators appearing in perturbative QCD 2 \rightarrow 2 scattering almost go on shell at low p_{\perp} , causing the differential cross sections to become very large, behaving roughly as

$$d\sigma_{2\rightarrow2} \propto \frac{dt}{t^2} \sim \frac{dp_{\perp}^2}{p_{\perp}^4}$$
 (38.13)

This cross section is an inclusive number. Thus, if a single hadron-hadron event contains two parton-parton interactions, it will "count" twice in $\sigma_{2\rightarrow 2}$ but only once in $\sigma_{\rm tot}$, and so on. In the limit that all the interactions are independent and equivalent, one would have

$$\sigma_{2\to 2}(p_{\perp \min}) = \langle n \rangle (p_{\perp \min}) \ \sigma_{\text{tot}} \ ,$$
 (38.14)

with $\langle n \rangle (p_{\perp \rm min})$ giving the average of a Poisson distribution in the number of parton-parton interactions above $p_{\perp \rm min}$ per hadron-hadron collision.

$$\mathcal{P}_n(p_{\perp \min}) = (\langle n \rangle (p_{\perp \min}))^n \frac{\exp\left(-\langle n \rangle (p_{\perp \min})\right)}{n!} . \tag{38.15}$$

 $^{^3\,}$ The QED elastic-scattering cross section diverges and is normally a non-default option in MC models.

This simple argument in fact expresses unitarity; instead of the total interaction cross section diverging as $p_{\perp \min} \to 0$ (which would violate unitarity), we have restated the problem so that it is now the number of MPI per collision that diverges, with the total cross section remaining finite. At LHC energies, the $2 \to 2$ scattering cross sections computed using the full LO QCD cross section folded with modern PDFs becomes larger than the total pp one for p_{\perp} values of order 4–5 GeV [74]. One therefore expects the average number of perturbative MPI to exceed unity at around that scale.

Two important ingredients remain to fully regulate the remaining divergence. Firstly, the interactions cannot use up more momentum than is available in the parent hadron. This suppresses the large-n tail of the estimate above. In PYTHIA-based models, the MPI are ordered in p_{\perp} , and the parton densities for each successive interaction are explicitly constructed so that the sum of x fractions can never be greater than unity. In the HERWIG models, instead the uncorrelated estimate of $\langle n \rangle$ above is used as an initial guess, but the generation of actual MPI is stopped once the energy-momentum conservation limit is reached.

The second ingredient invoked to suppress the number of interactions, at low p_{\perp} and x, is color screening; if the wavelength \sim $1/p_{\perp}$ of an exchanged colored parton becomes larger than a typical color-anticolor separation distance, it will only see an average color charge that vanishes in the limit $p_{\perp} \to 0$, hence leading to suppressed interactions. This provides an infrared cutoff for MPI similar to that provided by the hadronization scale for parton showers. A first estimate of the color-screening cutoff would be the proton size, $p_{\perp \rm min} \approx \hbar/r_p \approx 0.3\,{\rm GeV} \approx \Lambda_{\rm QCD}$, but empirically this appears to be far too low. In current models, one replaces the proton radius r_p in the above formula by a "typical color screening distance," i.e., an average size of a region within which the net compensation of a given color charge occurs. This number is not known from first principles [73] and is perceived of simply as an effective cutoff parameter. The simplest choice is to introduce a step function $\Theta(p_{\perp} - p_{\perp \min})$. Alternatively, one may note that the jet cross section is divergent like $\alpha_{\rm S}^2(p_\perp^2)/p_\perp^4$, cf. Eq. (38.13), and that therefore a factor

$$\frac{\alpha_{\rm S}^2(p_{\perp 0}^2 + p_{\perp}^2)}{\alpha_{\rm S}^2(p_{\perp}^2)} \frac{p_{\perp}^4}{(p_{\perp 0}^2 + p_{\perp}^2)^2}$$
(38.16)

would smoothly regulate the divergences, now with $p_{\perp 0}$ as the free parameter. Regardless of whether it is imposed as a smooth (PYTHIA and SHERPA) or steep (HERWIG++) function, this is effectively the main "tuning" parameter in such models.

Note that the numerical value obtained for the cross section depends upon the PDF set used, and therefore the optimal value to use for the cutoff will also depend on this choice. Note also that the cutoff does not have to be energy-independent. Higher energies imply that parton densities can be probed at smaller x values, where the number of partons rapidly increases. Partons then become closer packed and the color screening distance d decreases. The uncertainty on the energy and/or x scaling of the cutoff is a major concern when extrapolating between different collider energies [75].

We now turn to the origin of the observational fact that hard jets appear to sit on top of a higher "pedestal" of underlying activity than events with no hard jets. This is interpreted as a consequence of impact-parameter-dependence: in peripheral collisions, only a small fraction of events contain any high- p_{\perp} activity, whereas central collisions are more likely to contain at least one hard scattering; a high- p_{\perp} triggered sample will therefore be biased towards small impact parameters, b. The ability of a model to describe the shape of the pedestal (e.g. to describe both MB and UE distributions simultaneously) therefore depends upon its modeling of the b-dependence, and correspondingly the impact-parameter shape constitutes another main tuning parameter.

For each impact parameter b, the number of interactions $\tilde{n}(b)$ can then still be assumed to be distributed according to Eq. (38.15), again modulo momentum conservation, but now with the mean value of the Poisson distribution depending on impact parameter, $\langle \tilde{n}(b) \rangle$. This causes the final n-distribution (integrated over b) to be wider than a Poissonian

Finally, there are two perturbative modeling aspects which go beyond the introduction of MPI themselves: 1) parton showers off the MPI, and 2) perturbative parton-rescattering effects. Without showers, MPI models would generate very sharp peaks for backto-back MPI jets, caused by unshowered partons passed directly to the hadronization model. However, with the exception of the oldest PYTHIA6 model, all GPMC models do include such showers [15], and hence should exhibit more realistic (i.e., broader and more decorrelated) MPI jets. On the initial-state side, the main questions are whether and how correlated multi-parton densities are taken into account and, as discussed previously, how the showers are regulated at low p_{\perp} and/or low x. Although none of the MC models currently impose a rigorous correlated multi-parton evolution, all of them include some elementary aspects. The most significant for parton-level results is arguably momentum conservation, which is enforced explicitly in all the models. The so-called "interleaved" models [24] attempt to go a step further, generating an explicitly correlated multi-parton evolution in which flavor sum rules are imposed to conserve, e.g. the total numbers of valence and sea quarks [49].

Perturbative rescattering in the final state can occur if partons are allowed to undergo several distinct interactions, with showering activity possibly taking place in-between. This has so far not been studied extensively, but a first exploratory model is available [76]. In the initial state, parton rescattering/recombination effects have so far not been included in any of the GPMC models.

38.3.3. Bose-Einstein and Color-Reconnection Effects: In the context of e^+e^- collisions, Bose-Einstein (BE) correlations have mostly been discussed as a source of uncertainty on high-precision W mass determinations at LEP [77]. In hadron-hadron (and nucleus-nucleus) collisions, however, BE correlations are used extensively to study the space-time structure of hadronizing matter ("femtoscopy").

In MC models of hadronization, each string break and/or particle/cluster decay is normally factorized from all other ones. This reduces the number of variables that must be considered simultaneously, but also makes the introduction of correlations among particles from different breaks/decays intrinsically difficult to address. In the context of GPMCs, a few semi-classical models are available within the PYTHIA 6 and 8 generators [78], in which the BE effect is mimicked by an attractive interaction between pairs of identical particles in the final state, with no higher correlations included. This "force" acts after the decays of very short-lived particles, like $\rho,$ but before decays of longer-lived ones, like π^0 . The main differences between the variants of this model is the assumed shape of the correlation function and how overall momentum conservation is handled.

As discussed in Sec. 38.2, leading-color ("planar") color flows are used to set up the hadronizing systems (clusters or strings) at the hadronization stage. If the systems do not overlap significantly in space and time, subleading-color ambiguities and/or non-perturbative reconnections are expected to be small. However, if the density of displaced color charges is sufficiently high that several systems can overlap significantly, full-color and/or reconnection effects should become progressively larger.

In the specific context of MPI, a crucial question is how color is neutralized between different MPI systems, including the remnants. The large rapidity differences involved imply large invariant masses (though normally low p_{\perp}), and hence large amounts of (soft) particle production. Indeed, in the context of soft-inclusive physics, it is these "inter-system" strings/clusters that furnish the dominant particle-production mechanism, and hence their modeling is an essential part of the soft-physics description, affecting topics such as MB/UE multiplicity and p_{\perp} distributions, rapidity gaps, and precision mass measurements. A more comprehensive review of color-reconnection effects can be found in Ref. 15.

38.4. Parameters and Tuning

The achievable accuracy in GPMC models depends both on the inclusiveness of the chosen observable and on the sophistication of the simulation. An important driver for the latter is obviously the development of improved theoretical models, discussed in the preceding sections; but it also depends crucially on the available constraints on the remaining free parameters. Using existing data to constrain these is referred to as generator tuning.

Although MC models may appear to have a bewildering array of adjustable parameters, most of them only control relatively small (exclusive) details of the event generation. The majority of the (inclusive) physics is determined by only a few, very important ones, such as the value of $\alpha_{\rm S}$, in the perturbative domain, and the properties of the non-perturbative fragmentation functions, in the non-perturbative one. One may therefore take a factorized approach, first constraining the perturbative parameters and thereafter the non-perturbative ones, each ordered in a measure of their relative significance to the overall modeling.

At LO×LL, perturbation theory is doing well if it agrees with an IR safe measurement within 10%. It would therefore not make much sense to tune a GPMC beyond roughly 5% (it might even be dangerous, due to overfitting). The advent of NLO Monte Carlos may reduce this number slightly, but only for quantities for which one expects NLO precision. For LO Monte Carlos, distributions should be normalized to unity, since the NLO normalization is not tunable. For quantities governed by non-perturbative physics, uncertainties are larger. For some quantities, e.g. ones for which the underlying modeling is known to be poor, an order-of-magnitude agreement or worse may have to be accepted.

In the context of LO×LL GPMC tuning, subleading aspects of coupling-constant and PDF choices are relevant. In particular, one should be aware that the choice of QCD Λ parameter $\Lambda_{\rm MC}=1.569\Lambda_{\overline{\rm MS}}$ (for 5 active flavors) improves the predictions of coherent shower algorithms at the NLL level [79], and hence this scheme is typically considered the baseline for shower tuning. The question of LO vs. NLO PDFs is more involved [15], but it should be emphasized that the low-x gluon in particular is important for determining the level of the underlying event in MPI models (Sec. 38.3.2), and hence the MB/UE tuning (and energy scaling [75]) is linked to the choice of PDF in such models. Further issues and an example of a specific recipe that could be followed in a realistic set-up can be found in Ref. 80.

Recent years have seen the emergence of automated tools that attempt to reduce the amount of both computer and manpower required for tuning [81]. Automating the human expert input is more difficult. In the tools currently on the market, this question is addressed by a combination of input solicited from the generator authors (e.g., which parameters and ranges to consider, which observables constitute a complete set, etc) and a set of weights determining the relative priority given to each bin in each distribution. The field is still burgeoning, however, and future sophistications are to be expected. Nevertheless, the overall quality of the automated tunes appear to at least be competitive with the manual ones.

39. MONTE CARLO PARTICLE NUMBERING SCHEME

Revised April 2012 by J.-F. Arguin (LBNL, U. Montreal), L. Garren (Fermilab), F. Krauss (Durham U.), C.-J. Lin (LBNL), S. Navas (U. Granada), P. Richardson (Durham U.), and T. Sjöstrand (Lund U.).

The Monte Carlo particle numbering scheme presented here is intended to facilitate interfacing between event generators, detector simulators, and analysis packages used in particle physics. The numbering scheme was introduced in 1988 [1] and a revised version [2,3] was adopted in 1998 in order to allow systematic inclusion of quark model states which are as yet undiscovered and hypothetical particles such as SUSY particles. The numbering scheme is used in several event generators, e.q. HERWIG, PYTHIA, and SHERPA, and interfaces, e.g. /HEPEVT/ and HepMC.

The general form is a 7-digit number:

$$\pm n\; n_r\; n_L\; n_{q_1}\; n_{q_2}\; n_{q_3}\; n_J\;.$$

This encodes information about the particle's spin, flavor content, and internal quantum numbers. The details are as follows:

- 1. Particles are given positive numbers, antiparticles negative numbers. The PDG convention for mesons is used, so that K^+ and B^+ are particles.
- 2. Quarks and leptons are numbered consecutively starting from 1 and 11 respectively; to do this they are first ordered by family and within families by weak isospin.
- 3. In composite quark systems (diquarks, mesons, and baryons) $n_{q_{1-3}}$ are quark numbers used to specify the quark content, while the rightmost digit $n_J = 2J + 1$ gives the system's spin (except for the K_S^0 and K_L^0). The scheme does not cover particles of spin
- 4. Diquarks have 4-digit numbers with $n_{q_1} \geq n_{q_2}$ and $n_{q_3} = 0$. 5. The numbering of mesons is guided by the nonrelativistic (L–S decoupled) quark model, as listed in Tables 14.2 and 14.3.
 - a. The numbers specifying the meson's quark content conform to the convention $n_{q_1}=0$ and $n_{q_2}\geq n_{q_3}.$ The special case K_I^0 is the sole exception to this rule.
 - b. The quark numbers of flavorless, light (u, d, s) mesons are: 11 for the member of the isotriplet (π^0, ρ^0, \ldots) , 22 for the lighter isosinglet (η, ω, \ldots) , and 33 for the heavier isosinglet (η', ϕ, \ldots) . Since isosinglet mesons are often large mixtures of $u\overline{u} + d\overline{d}$ and $s\overline{s}$ states, 22 and 33 are assigned by mass and do not necessarily specify the dominant quark composition.
 - c. The special numbers 310 and 130 are given to the K_S^0 and K_L^0 respectively.
 - d. The fifth digit n_L is reserved to distinguish mesons of the same total (J) but different spin (S) and orbital (L) angular momentum quantum numbers. For J > 0 the numbers are: $(L,S) = (J-1,1) n_L = 0, (J,0) n_L = 1, (J,1) n_L = 2$ and (J+1,1) $n_L=3$. For the exceptional case J=0 the numbers are (0,0) $n_L = 0$ and (1,1) $n_L = 1$ (i.e. $n_L = L$). See Table 39.1.

Table 39.1: Meson numbering logic. Here qq stands for $n_{q2} n_{q3}$

| | L = J | -1, S | ' = 1 | L = J | S = 0 | 0 | L = J | $S = \frac{1}{2}$ | 1 | L = J | +1, i | S = 1 |
|----------------|-------|----------|-------|-------|----------|---|-------|-------------------|---|-------|----------|-------|
| \overline{J} | code | J^{PC} | L | code | J^{PC} | L | code | J^{PC} | L | code | J^{PC} | L |
| 0 | _ | _ | _ | | | | _ | | | | | 1 |
| 1 | 00qq3 | 1 | | | | | 20qq3 | | | 30qq3 | $1^{}$ | 2 |
| 2 | 00qq5 | 2^{++} | 1 | 10qq5 | 2^{-+} | 2 | 20qq5 | $2^{}$ | 2 | 30qq5 | 2^{++} | 3 |
| | 00qq7 | | | | | | 20qq7 | | | 30qq7 | | 4 |
| 4 | 00qq9 | 4++ | 3 | 10qq9 | 4^{-+} | 4 | 20qq9 | 4 | 4 | 30qq9 | 4++ | 5 |

e. If a set of physical mesons correspond to a (non-negligible) mixture of basis states, differing in their internal quantum numbers, then the lightest physical state gets the smallest basis state number. For example the $K_1(1270)$ is numbered 10313 (1 $^{1}P_{1}$ K_{1B}) and the $K_{1}(1400)$ is numbered 20313 $(1^3P_1 K_{1A}).$

- f. The sixth digit n_r is used to label mesons radially excited above the ground state.
- g. Numbers have been assigned for complete $n_r = 0$ S- and P-wave multiplets, even where states remain to be identified.
- h. In some instances assignments within the $q\bar{q}$ meson model are only tentative; here best guess assignments are made.
- i. Many states appearing in the Meson Listings are not yet assigned within the $q\bar{q}$ model. Here $n_{q_{2}-3}$ and n_{J} are assigned according to the state's likely flavors and spin; all such unassigned light isoscalar states are given the flavor code 22. Within these groups $n_L = 0, 1, 2, ...$ is used to distinguish states of increasing mass. These states are flagged using n = 9. It is to be expected that these numbers will evolve as the nature of the states are elucidated. Codes are assigned to all mesons which are listed in the one-page table at the end of the Meson Summary Table as long as they have a prefered or established spin. Additional heavy meson states expected from heavy quark spectroscopy are also assigned
- 6. The numbering of baryons is again guided by the nonrelativistic quark model, see Table 14.6. This numbering scheme is illustrated through a few examples in Table 39.2.
 - a. The numbers specifying a baryon's quark content are such
 - that in general $n_{q_1} \ge n_{q_2} \ge n_{q_3}$. b. Two states exist for J=1/2 baryons containing 3 different types of quarks. In the lighter baryon $(\Lambda, \Xi, \Omega, ...)$ the light quarks are in an antisymmetric (J=0) state while for the heavier baryon $(\Sigma^0, \Xi', \Omega', ...)$ they are in a symmetric (J=1) state. In this situation n_{q_2} and n_{q_3} are reversed for the lighter state, so that the smaller number corresponds to the lighter baryon.
 - c. For excited baryons a scheme is adopted, where the n_r label is used to denote the excitation bands in the harmonic oscillator model, see Sec. 14.4. Using the notation employed there, n_r is given by the N-index of the D_N band identifier.
 - d. Further degeneracies of excited hadron multiplets with the same excitation number n_r and spin J are lifted by labelling such multiplets with the n_L index according to their mass, as given by its N or Δ -equivalent.
 - e. In such excited multiplets extra singlets may occur, the $\Lambda(1520)$ being a prominent example. In such cases the ordering is reversed such that the heaviest quark label is pushed to the last position: $n_{q_3} > n_{q_1} > n_{q_2}$.
 - f. For pentaquark states $n=9, n_r n_L n_{q_1} n_{q_2}$ gives the four quark numbers in order $n_r \geq n_L \geq n_{q_1} \geq n_{q_2}$, n_{q_3} gives the antiquark number, and $n_J = 2J+1$, with the assumption that J = 1/2 for the states currently reported.
- 7. The gluon, when considered as a gauge boson, has official number 21. In codes for glueballs, however, 9 is used to allow a notation in close analogy with that of hadrons.
- 8. The pomeron and odderon trajectories and a generic reggeon trajectory of states in QCD are assigned codes 990, 9990, and 110 respectively, where the final 0 indicates the indeterminate nature of the spin, and the other digits reflect the expected "valence" flavor content. We do not attempt a complete classification of all reggeon trajectories, since there is currently no need to distinguish a specific such trajectory from its lowest-lying member.
- 9. Two-digit numbers in the range 21-30 are provided for the Standard Model gauge bosons and Higgs.
- 10. Codes 81-100 are reserved for generator-specific pseudoparticles and concepts.
- 11. The search for physics beyond the Standard Model is an active area, so these codes are also standardized as far as possible.
 - a. A standard fourth generation of fermions is included by analogy with the first three.
 - b. The graviton and the boson content of a two-Higgs-doublet scenario and of additional $SU(2)\times U(1)$ groups are found in the range 31-40.
 - c. "One-of-a-kind" exotic particles are assigned numbers in the range 41-80.
 - Fundamental supersymmetric particles are identified by adding a nonzero \boldsymbol{n} to the particle number. The superpartner of a boson or a left-handed fermion has n = 1 while the

Table 39.2: Some examples of octet (top) and decuplet (bottom) members for the numbering scheme for excited baryons. Here qqq stands for $n_{q_1}n_{q_2}n_{q_3}$. See the text for the definition of the notation. The numbers in parenthesis correspond to the mass of the baryons. The states marked as (?) are not experimentally confirmed.

superpartner of a right-handed fermion has n=2. When mixing occurs, such as between the winos and charged Higgsinos to give charginos, or between left and right sfermions, the lighter physical state is given the smaller basis state number.

- e. Technicolor states have n=3, with technifermions treated like ordinary fermions. States which are ordinary color singlets have $n_r=0$. Color octets have $n_r=1$. If a state has non-trivial quantum numbers under the topcolor groups $\mathrm{SU}(3)_1 \times \mathrm{SU}(3)_2$, the quantum numbers are specified by tech, ij , where i and j are 1 or 2. n_L is then 2i+j. The coloron, V_8 , is a heavy gluon color octet and thus is 3100021.
- f. Excited (composite) quarks and leptons are identified by setting n=4 and $n_r=0$.
- Within several scenarios of new physics, it is possible to have colored particles sufficiently long-lived for color-singlet hadronic states to form around them. In the context of supersymmetric scenarios, these states are called R-hadrons, since they carry odd R-parity. R-hadron codes, defined here, should be viewed as templates for corresponding codes also in other scenarios, for any long-lived particle that is either an unflavored color octet or a flavored color triplet. The R-hadron code is obtained by combining the SUSY particle code with a code for the light degrees of freedom, with as many intermediate zeros removed from the former as required to make place for the latter at the end. (To exemplify, a sparticle $n00000n_{\tilde{q}}$ combined with quarks q_1 and q_2 obtains code $n00n_{\tilde{q}}n_{q_1}n_{q_2}n_J$.) Specifically, the new-particle spin decouples in the limit of large masses, so that the final n_J digit is defined by the spin state of the light-quark system alone. An appropriate number of n_q digits is used to define the ordinary-quark content. As usual, 9 rather than 21 is used to denote a gluon/gluino in composite states. The sign of the hadron agrees with that of the constituent new particle (a color triplet) where there is a distinct new antiparticle, and else is defined as for normal hadrons. Particle names are R with the flavor content as lower index.
- h. A black hole in models with extra dimensions has code 5000040. Kaluza-Klein excitations in models with extra dimensions have n=5 or n=6, to distinquish excitations of left- or right-handed fermions or, in case of mixing, the lighter or heavier state (cf. 11d). The nonzero n_r digit gives the radial excitation number, in scenarios where the level spacing allow these to be distinguished. Should the model also contain supersymmetry, excited SUSY states would be denoted by an $n_r>0$, with n=1 or 2 as usual. Should some colored states be long-lived enough that hadrons would form around them, the coding strategy of 11g applies, with the initial two nn_r digits preserved in the combined code.

- i. Magnetic monopoles and dyons are assumed to have one unit of Dirac monopole charge and a variable integer number $n_{q1}n_{q2}n_{q3}$ units of electric charge. Codes $411n_{q1}n_{q2}n_{q3}0$ are then used when the magnetic and electrical charge sign agree and $412n_{q1}n_{q2}n_{q3}0$ when they disagree, with the overall sign of the particle set by the magnetic charge. For now no spin information is provided.
- 12. Occasionally program authors add their own states. To avoid confusion, these should be flagged by setting $nn_T = 99$.
- 13. Concerning the non-99 numbers, it may be noted that only quarks, excited quarks, squarks, and diquarks have $n_{q_3}=0$; only diquarks, baryons (including pentaquarks), and the odderon have $n_{q_1}\neq 0$; and only mesons, the reggeon, and the pomeron have $n_{q_1}=0$ and $n_{q_2}\neq 0$. Concerning mesons (not antimesons), if n_{q_1} is odd then it labels a quark and an antiquark if even.
- 14. Nuclear codes are given as 10-digit numbers ±10LZZZAAAI. For a (hyper)nucleus consisting of n_p protons, n_n neutrons and n_Λ Λ's, A = n_p + n_n + n_Λ gives the total baryon number, Z = n_p the total charge and L = n_Λ the total number of strange quarks. I gives the isomer level, with I = 0 corresponding to the ground state and I > 0 to excitations, see [4], where states denoted m, n, p, q translate to I = 1 4. As examples, the deuteron is 1000010020 and ²³⁵U is 1000922350. To avoid ambiguities, nuclear codes should not be applied to a single hadron, like p, n or Λ⁰, where quark-contents-based codes already exist.

This text and full lists of particle numbers, including excited baryons particles from physics beyond the standard model, can be found on the WWW [5]. The StdHep Monte Carlo standardization project [6] maintains the list of PDG particle numbers, as well as numbering schemes from most event generators and software to convert between the different schemes.

Footnotes to the Tables:

- a) Particulary in the third generation, the left and right sfermion states may mix, as shown. The lighter mixed state is given the smaller number.

 b) The physical $\widetilde{\chi}$ states are admixtures of the pure $\widetilde{\gamma}$, \widetilde{Z}^0 , \widetilde{W}^+ , \widetilde{H}^0_1 , \widetilde{H}^0_2 , and \widetilde{H}^+ states.

 c) Σ^* and Ξ^* are alternate names for $\Sigma(1385)$ and $\Xi(1530)$.

40. CLEBSCH-GORDAN COEFFICIENTS, SPHERICAL HARMONICS, AND d FUNCTIONS

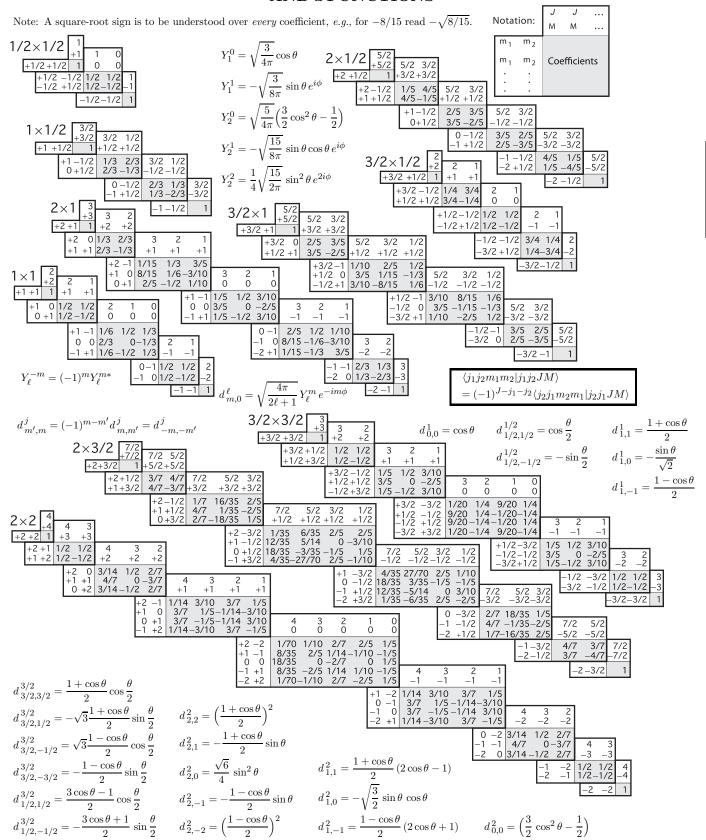

Figure 40.1: The sign convention is that of Wigner (*Group Theory*, Academic Press, New York, 1959), also used by Condon and Shortley (*The Theory of Atomic Spectra*, Cambridge Univ. Press, New York, 1953), Rose (*Elementary Theory of Angular Momentum*, Wiley, New York, 1957), and Cohen (*Tables of the Clebsch-Gordan Coefficients*, North American Rockwell Science Center, Thousand Oaks, Calif., 1974).

41. SU(3) ISOSCALAR FACTORS AND REPRESENTATION MATRICES

Written by R.L. Kelly (LBNL).

The most commonly used SU(3) isoscalar factors, corresponding to the singlet, octet, and decuplet content of $8\otimes 8$ and $10\otimes 8$, are shown at the right. The notation uses particle names to identify the coefficients, so that the pattern of relative couplings may be seen at a glance. We illustrate the use of the coefficients below. See J.J de Swart, Rev. Mod. Phys. **35**, 916 (1963) for detailed explanations and phase conventions.

 $A \sqrt{\ }$ is to be understood over every integer in the matrices; the exponent 1/2 on each matrix is a reminder of this. For example, the $\Xi \to \Omega K$ element of the $10 \to 10 \otimes 8$ matrix is $-\sqrt{6}/\sqrt{24} = -1/2$.

Intramultiplet relative decay strengths may be read directly from the matrices. For example, in decuplet \rightarrow octet + octet decays, the ratio of $\Omega^* \rightarrow \Xi \overline{K}$ and $\Delta \rightarrow N\pi$ partial widths is, from the $10 \rightarrow 8 \times 8$ matrix,

$$\frac{\Gamma\left(\Omega^* \to \Xi \overline{K}\right)}{\Gamma\left(\Delta \to N\pi\right)} = \frac{12}{6} \times \text{ (phase space factors)} . \tag{41.1}$$

Including isospin Clebsch-Gordan coefficients, we obtain, e.g.,

$$\frac{\Gamma(\Omega^{*-} \to \Xi^0 K^-)}{\Gamma(\Delta^+ \to p \, \pi^0)} = \frac{1/2}{2/3} \times \frac{12}{6} \times p.s.f. = \frac{3}{2} \times p.s.f. \tag{41.2}$$

Partial widths for $8 \to 8 \otimes 8$ involve a linear superposition of 8_1 (symmetric) and 8_2 (antisymmetric) couplings. For example,

$$\Gamma(\Xi^* \to \Xi \pi) \sim \left(-\sqrt{\frac{9}{20}} g_1 + \sqrt{\frac{3}{12}} g_2\right)^2$$
 (41.3)

The relations between g_1 and g_2 (with de Swart's normalization) and the standard D and F couplings that appear in the interaction Lagrangian,

$$\mathcal{L} = -\sqrt{2} D \operatorname{Tr}(\{\overline{B}, B\}M) + \sqrt{2} F \operatorname{Tr}([\overline{B}, B]M) , \qquad (41.4)$$

where $[\overline{B}, B] \equiv \overline{B}B - B\overline{B}$ and $\{\overline{B}, B\} \equiv \overline{B}B + B\overline{B}$, are

$$D = \frac{\sqrt{30}}{40} g_1 , \qquad F = \frac{\sqrt{6}}{24} g_2 . \tag{41.5}$$

Thus, for example,

$$\Gamma(\Xi^* \to \Xi \pi) \sim (F - D)^2 \sim (1 - 2\alpha)^2$$
, (41.6)

where $\alpha \equiv F/(D+F)$. (This definition of α is de Swart's. The alternative D/(D+F), due to Gell-Mann, is also used.)

The generators of SU(3) transformations, λ_a (a=1,8), are 3×3 matrices that obey the following commutation and anticommutation relationships:

$$[\lambda_a, \lambda_b] \equiv \lambda_a \lambda_b - \lambda_b \lambda_a = 2i f_{abc} \lambda_c \tag{41.7}$$

$$\{\lambda_a, \lambda_b\} \equiv \lambda_a \lambda_b + \lambda_b \lambda_a = \frac{4}{3} \delta_{ab} I + 2 d_{abc} \lambda_c , \qquad (41.8)$$

where I is the 3×3 identity matrix, and δ_{ab} is the Kronecker delta symbol. The f_{abc} are odd under the permutation of any pair of indices, while the d_{abc} are even. The nonzero values are

$$1 \to 8 \otimes 8$$

$$(\Lambda) \rightarrow (N\overline{K} \Sigma \pi \Lambda \eta \Xi K) = \frac{1}{\sqrt{8}} (2 \ 3 \ -1 \ -2)^{1/2}$$

 $8_1 \to 8 \otimes 8$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \rightarrow \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{20}} \begin{pmatrix} 9 & -1 & -9 & -1 \\ -6 & 0 & 4 & 4 & -6 \\ 2 & -12 & -4 & -2 \\ 9 & -1 & -9 & -1 \end{pmatrix}^{1/2}$$

$$8_2 o 8 \otimes 8$$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \rightarrow \begin{pmatrix} N\pi & N\eta & \Sigma K & \Lambda K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ N\overline{K} & \Sigma\pi & \Lambda\eta & \Xi K \\ \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} 3 & 3 & 3 & -3 \\ 2 & 8 & 0 & 0 & -2 \\ 6 & 0 & 0 & 6 \\ 3 & 3 & 3 & -3 \end{pmatrix}^{1/2}$$

$$\mathbf{10} \rightarrow \mathbf{8} \otimes \mathbf{8}$$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \rightarrow \begin{pmatrix} N\pi & \Sigma K \\ N\overline{K} & \Sigma\pi & \Lambda\pi & \Sigma\eta & \Xi K \\ \Sigma\overline{K} & \Lambda\overline{K} & \Xi\pi & \Xi\eta \\ \Xi\overline{K} \end{pmatrix} = \frac{1}{\sqrt{12}} \begin{pmatrix} -6 & 6 & \\ -2 & 2 & -3 & 3 & 2 \\ 3 & -3 & 3 & 3 & \\ 12 & & & 12 \end{pmatrix}^{1/2}$$

$$8 \rightarrow 10 \otimes 8$$

$$\begin{pmatrix} N \\ \Sigma \\ \Lambda \\ \Xi \end{pmatrix} \rightarrow \begin{pmatrix} \Delta\pi & \Sigma K \\ \Sigma\pi & \Sigma\eta & \Xi K \\ \Sigma\pi & \Xi K \\ \Sigma\overline{K} & \Xi\pi & \Xi\eta & \Omega K \end{pmatrix} = \frac{1}{\sqrt{15}} \begin{pmatrix} -12 & 3 \\ 8 & -2 & -3 & 2 \\ -9 & 6 \\ 3 & -3 & -3 & 6 \end{pmatrix}^{1/2}$$

$$10 \rightarrow 10 \otimes 8$$

$$\begin{pmatrix} \Delta \\ \Sigma \\ \Xi \\ \Omega \end{pmatrix} \rightarrow \begin{pmatrix} \Delta \pi & \Delta \eta & \Sigma K \\ \Delta \overline{K} & \Sigma \pi & \Sigma \eta & \Xi K \\ \Sigma \overline{K} & \Xi \pi & \Xi \eta & \Omega K \\ \Xi \overline{K} & \Omega \eta \end{pmatrix} \qquad = \frac{1}{\sqrt{24}} \begin{pmatrix} 15 & 3 & -6 \\ 8 & 8 & 0 & -8 \\ 12 & 3 & -3 & -6 \\ 12 & -12 \end{pmatrix}^{1/2}$$

| abc | f_{abc} | abc | d_{abc} | \underline{abc} | d_{abc} |
|-----|--------------|-----|--------------|-------------------|------------------|
| 123 | 1 | 118 | $1/\sqrt{3}$ | 355 | 1/2 |
| 147 | 1/2 | 146 | 1/2 | 366 | -1/2 |

| 257 | 1/2 | 247 | -1/2 | 558 | $-1/(2\sqrt{3})$ |
| 345 | 1/2 | 256 | 1/2 | 668 | $-1/(2\sqrt{3})$ |
| 367 | -1/2 | 338 | $1/\sqrt{3}$ | 778 | $-1/(2\sqrt{3})$ |
| 458 | $\sqrt{3}/2$ | 344 | 1/2 | 888 | $-1/\sqrt{3}$ |
| 678 | $\sqrt{3}/2$ | | | | |

The λ_a 's are

$$\lambda_{1} = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_{2} = \begin{pmatrix} 0 & -i & 0 \\ i & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \quad \lambda_{3} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 0 \end{pmatrix}$$

$$\lambda_{4} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{pmatrix} \quad \lambda_{5} = \begin{pmatrix} 0 & 0 & -i \\ 0 & 0 & 0 \\ i & 0 & 0 \end{pmatrix} \quad \lambda_{6} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}$$

$$\lambda_{7} = \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -i \\ 0 & i & 0 \end{pmatrix} \quad \lambda_{8} = \frac{1}{\sqrt{3}} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{pmatrix}$$

Equation (41.7) defines the Lie algebra of SU(3). A general d-dimensional representation is given by a set of $d \times d$ matrices satisfying Eq. (41.7) with the f_{abc} given above. Equation (41.8) is specific to the defining 3-dimensional representation.

42. SU(n) MULTIPLETS AND YOUNG DIAGRAMS

Written by C.G. Wohl (LBNL).

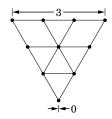

This note tells (1) how SU(n) particle multiplets are identified or labeled, (2) how to find the number of particles in a multiplet from its label, (3) how to draw the Young diagram for a multiplet, and (4) how to use Young diagrams to determine the overall multiplet structure of a composite system, such as a 3-quark or a meson-baryon system.

In much of the literature, the word "representation" is used where we use "multiplet," and "tableau" is used where we use "diagram."

42.1. Multiplet labels

An SU(n) multiplet is uniquely identified by a string of (n-1) nonnegative integers: $(\alpha, \beta, \gamma, \ldots)$. Any such set of integers specifies a multiplet. For an SU(2) multiplet such as an isospin multiplet, the single integer α is the number of *steps* from one end of the multiplet to the other (*i.e.*, it is one fewer than the number of particles in the multiplet). In SU(3), the two integers α and β are the numbers of steps across the top and bottom levels of the multiplet diagram. Thus the labels for the SU(3) octet and decuplet

are (1,1) and (3,0). For larger n, the interpretation of the integers in terms of the geometry of the multiplets, which exist in an (n-1)-dimensional space, is not so readily apparent.

The label for the SU(n) singlet is $(0,0,\ldots,0)$. In a flavor SU(n), the n quarks together form a $(1,0,\ldots,0)$ multiplet, and the n antiquarks belong to a $(0,\ldots,0,1)$ multiplet. These two multiplets are conjugate to one another, which means their labels are related by $(\alpha,\beta,\ldots) \leftrightarrow (\ldots,\beta,\alpha)$.

42.2. Number of particles

The number of particles in a multiplet, $N = N(\alpha, \beta, ...)$, is given as follows (note the pattern of the equations).

In SU(2), $N = N(\alpha)$ is

$$N = \frac{(\alpha + 1)}{1} \ . \tag{42.1}$$

In SU(3), $N = N(\alpha, \beta)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\alpha+\beta+2)}{2} . \tag{42.2}$$

In SU(4), $N = N(\alpha, \beta, \gamma)$ is

$$N = \frac{(\alpha+1)}{1} \cdot \frac{(\beta+1)}{1} \cdot \frac{(\gamma+1)}{1} \cdot \frac{(\gamma+1)}{2} \cdot \frac{(\alpha+\beta+2)}{2} \cdot \frac{(\beta+\gamma+2)}{2} \cdot \frac{(\alpha+\beta+\gamma+3)}{3} \ . \tag{42.3}$$

Note that in Eq. (42.3) there is no factor with $(\alpha + \gamma + 2)$: only a consecutive sequence of the label integers appears in any factor. One more example should make the pattern clear for any SU(n). In SU(5), $N = N(\alpha, \beta, \gamma, \delta)$ is

$$\begin{split} N &= \frac{(\alpha + 1)}{1} \cdot \frac{(\beta + 1)}{1} \cdot \frac{(\gamma + 1)}{1} \cdot \frac{(\delta + 1)}{1} \cdot \frac{(\alpha + \beta + 2)}{2} \cdot \frac{(\beta + \gamma + 2)}{2} \\ &\times \frac{(\gamma + \delta + 2)}{2} \cdot \frac{(\alpha + \beta + \gamma + 3)}{3} \cdot \frac{(\beta + \gamma + \delta + 3)}{3} \cdot \frac{(\alpha + \beta + \gamma + \delta + 4)}{4} (42.4) \end{split}$$

From the symmetry of these equations, it is clear that multiplets that are conjugate to one another have the same number of particles, but so can other multiplets. For example, the SU(4) multiplets (3,0,0) and (1,1,0) each have 20 particles. Try the equations and see.

42.3. Young diagrams

A Young diagram consists of an array of boxes (or some other symbol) arranged in one or more left-justified rows, with each row being at least as long as the row beneath. The correspondence between a diagram and a multiplet label is: The top row juts out α boxes to the right past the end of the second row, the second row juts out β boxes to the right past the end of the third row, etc. A diagram in SU(n) has at most n rows. There can be any number of "completed" columns of n boxes buttressing the left of a diagram; these don't affect the label. Thus in SU(3) the diagrams

represent the multiplets (1,0), (0,1), (0,0), (1,1), and (3,0). In any SU(n), the quark multiplet is represented by a single box, the antiquark multiplet by a column of (n-1) boxes, and a singlet by a completed column of n boxes.

42.4. Coupling multiplets together

The following recipe tells how to find the multiplets that occur in coupling two multiplets together. To couple together more than two multiplets, first couple two, then couple a third with each of the multiplets obtained from the first two, etc.

First a definition: A sequence of the letters a,b,c,\ldots is admissible if at any point in the sequence at least as many a's have occurred as b's, at least as many b's have occurred as c's, etc. Thus abcd and aabcb are admissible sequences and abb and acb are not. Now the recipe:

- (a) Draw the Young diagrams for the two multiplets, but in one of the diagrams replace the boxes in the first row with a's, the boxes in the second row with b's, etc. Thus, to couple two SU(3) octets (such as the π -meson octet and the baryon octet), we start with \square and
- $^{\sf a}$ $^{\sf a}$ $^{\sf a}$. The unlettered diagram forms the $upper\ left$ -hand corner of all the enlarged diagrams constructed below.
- (b) Add the a's from the lettered diagram to the right-hand ends of the rows of the unlettered diagram to form all possible legitimate Young diagrams that have no more than one a per column. In general, there will be several distinct diagrams, and all the a's appear in each diagram. At this stage, for the coupling of the two SU(3) octets, we have:

- (c) Use the b's to further enlarge the diagrams already obtained, subject to the same rules. Then throw away any diagram in which the full sequence of letters formed by reading right to left in the first row, then the second row, etc., is not admissible.
 - (d) Proceed as in (c) with the c's (if any), etc.

The final result of the coupling of the two SU(3) octets is:

Here only the diagrams with admissible sequences of a's and b's and with fewer than four rows (since n=3) have been kept. In terms of multiplet labels, the above may be written

$$(1,1) \otimes (1,1) = (2,2) \oplus (3,0) \oplus (0,3) \oplus (1,1) \oplus (1,1) \oplus (0,0)$$
.

In terms of numbers of particles, it may be written

$$\mathbf{8} \otimes \mathbf{8} = \mathbf{27} \oplus \mathbf{10} \oplus \overline{\mathbf{10}} \oplus \mathbf{8} \oplus \mathbf{8} \oplus \mathbf{1} \ .$$

The product of the numbers on the left here is equal to the sum on the right, a useful check. (See also Sec. 14 on the Quark Model.)

43. KINEMATICS

Revised January 2000 by J.D. Jackson (LBNL) and June 2008 by D.R. Tovey (Sheffield).

Throughout this section units are used in which $\hbar=c=1$. The following conversions are useful: $\hbar c=197.3$ MeV fm, $(\hbar c)^2=0.3894$ (GeV)² mb.

43.1. Lorentz transformations

The energy E and 3-momentum p of a particle of mass m form a 4-vector p=(E,p) whose square $p^2\equiv E^2-|p|^2=m^2$. The velocity of the particle is $\beta=p/E$. The energy and momentum (E^*,p^*) viewed from a frame moving with velocity β_f are given by

$$\begin{pmatrix} E^* \\ p_{\parallel}^* \end{pmatrix} = \begin{pmatrix} \gamma_f & -\gamma_f \beta_f \\ -\gamma_f \beta_f & \gamma_f \end{pmatrix} \begin{pmatrix} E \\ p_{\parallel} \end{pmatrix} \;, \quad p_T^* = p_T \;, \tag{43.1}$$

where $\gamma_f = (1-\beta_f^2)^{-1/2}$ and p_T (p_{\parallel}) are the components of p perpendicular (parallel) to β_f . Other 4-vectors, such as the spacetime coordinates of events, of course transform in the same way. The scalar product of two 4-momenta $p_1 \cdot p_2 = E_1 E_2 - p_1 \cdot p_2$ is invariant (frame independent).

43.2. Center-of-mass energy and momentum

In the collision of two particles of masses m_1 and m_2 the total center-of-mass energy can be expressed in the Lorentz-invariant form

$$E_{\rm cm} = \left[(E_1 + E_2)^2 - (\mathbf{p}_1 + \mathbf{p}_2)^2 \right]^{1/2} ,$$

= $\left[m_1^2 + m_2^2 + 2E_1E_2(1 - \beta_1\beta_2\cos\theta) \right]^{1/2} ,$ (43.2)

where θ is the angle between the particles. In the frame where one particle (of mass m_2) is at rest (lab frame),

$$E_{\rm cm} = (m_1^2 + m_2^2 + 2E_{1\,\rm lab}\,m_2)^{1/2} \ . \tag{43.3}$$

The velocity of the center-of-mass in the lab frame is

$$\beta_{\rm cm} = p_{\rm lab}/(E_{1\,\rm lab} + m_2) ,$$
 (43.4)

where $p_{\mathrm{lab}} \equiv p_{\mathrm{1\,lab}}$ and

$$\gamma_{\rm cm} = (E_{1 \, \rm lab} + m_2)/E_{\rm cm} \ .$$
 (43.5)

The c.m. momenta of particles 1 and 2 are of magnitude

$$p_{\rm cm} = p_{\rm lab} \frac{m_2}{E_{\rm cm}} \ .$$
 (43.6)

For example, if a $0.80~{\rm GeV}/c$ kaon beam is incident on a proton target, the center of mass energy is $1.699~{\rm GeV}$ and the center of mass momentum of either particle is $0.442~{\rm GeV}/c$. It is also useful to note that

$$E_{\rm cm} dE_{\rm cm} = m_2 dE_{1 \, \rm lab} = m_2 \, \beta_{1 \, \rm lab} \, dp_{\rm lab} \ .$$
 (43.7)

43.3. Lorentz-invariant amplitudes

The matrix elements for a scattering or decay process are written in terms of an invariant amplitude $-i\mathcal{M}$. As an example, the S-matrix for $2 \to 2$ scattering is related to \mathcal{M} by

$$\langle p_1' p_2' | S | p_1 p_2 \rangle = I - i(2\pi)^4 \, \delta^4(p_1 + p_2 - p_1' - p_2')$$

$$\times \frac{\mathscr{M}(p_1, p_2; p_1', p_2')}{(2E_1)^{1/2} \, (2E_2)^{1/2} \, (2E_1')^{1/2} \, (2E_2')^{1/2}} \, . \quad (43.8)$$

The state normalization is such that

$$\langle p'|p\rangle = (2\pi)^3 \delta^3(\boldsymbol{p} - \boldsymbol{p}') . \tag{43.9}$$

43.4. Particle decays

The partial decay rate of a particle of mass M into n bodies in its rest frame is given in terms of the Lorentz-invariant matrix element $\mathcal M$ by

$$d\Gamma = \frac{(2\pi)^4}{2M} |\mathcal{M}|^2 d\Phi_n (P; p_1, \dots, p_n), \tag{43.10}$$

where $d\Phi_n$ is an element of n-body phase space given by

$$d\Phi_n(P; p_1, \dots, p_n) = \delta^4 \left(P - \sum_{i=1}^n p_i \right) \prod_{i=1}^n \frac{d^3 p_i}{(2\pi)^3 2E_i} . \tag{43.11}$$

This phase space can be generated recursively, viz.

$$d\Phi_n(P; p_1, ..., p_n) = d\Phi_j(q; p_1, ..., p_j)$$

$$\times d\Phi_{n-j+1}(P; q, p_{j+1}, \dots, p_n)(2\pi)^3 dq^2,$$
 (43.12)

where $q^2 = (\sum_{i=1}^j E_i)^2 - \left|\sum_{i=1}^j \mathbf{p}_i\right|^2$. This form is particularly useful in the case where a particle decays into another particle that subsequently decays.

43.4.1. Survival probability: If a particle of mass M has mean proper lifetime τ (= $1/\Gamma$) and has momentum (E, p), then the probability that it lives for a time t_0 or greater before decaying is given by

$$P(t_0) = e^{-t_0 \Gamma/\gamma} = e^{-Mt_0 \Gamma/E}$$
, (43.13)

and the probability that it travels a distance x_0 or greater is

$$P(x_0) = e^{-Mx_0 |\Gamma||p|}. (43.14)$$

43.4.2. Two-body decays:

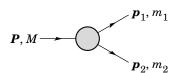

Figure 43.1: Definitions of variables for two-body decays.

In the rest frame of a particle of mass M, decaying into 2 particles labeled 1 and 2,

$$E_1 = \frac{M^2 - m_2^2 + m_1^2}{2M} , (43.15)$$

$$|p_1| = |p_2|$$

$$= \frac{\left[\left(M^2 - (m_1 + m_2)^2\right)\left(M^2 - (m_1 - m_2)^2\right)\right]^{1/2}}{2M}, \quad (43.16)$$

and

$$d\Gamma = \frac{1}{32\pi^2} |\mathcal{M}|^2 \frac{|\mathbf{p}_1|}{M^2} d\Omega$$
, (43.17)

where $d\Omega = d\phi_1 d(\cos \theta_1)$ is the solid angle of particle 1. The invariant mass M can be determined from the energies and momenta using Eq. (43.2) with $M = E_{\rm cm}$.

43.4.3. Three-body decays:

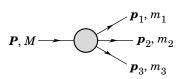

Figure 43.2: Definitions of variables for three-body decays.

Defining $p_{ij}=p_i+p_j$ and $m_{ij}^2=p_{ij}^2$, then $m_{12}^2+m_{23}^2+m_{13}^2=M^2+m_1^2+m_2^2+m_3^2$ and $m_{12}^2=(P-p_3)^2=M^2+m_3^2-2ME_3$, where E_3 is the energy of particle 3 in the rest frame of M. In that frame, the momenta of the three decay particles lie in a plane. The relative orientation of these three momenta is fixed if their energies are known. The momenta can therefore be specified in space by giving three Euler angles (α, β, γ) that specify the orientation of the final system relative to the initial particle [1]. Then

$$d\Gamma = \frac{1}{(2\pi)^5} \frac{1}{16M} |\mathcal{M}|^2 dE_1 dE_2 d\alpha d(\cos \beta) d\gamma . \tag{43.18}$$

Alternatively

$$d\Gamma = \frac{1}{(2\pi)^5} \frac{1}{16M^2} |\mathcal{M}|^2 |\mathbf{p}_1^*| |\mathbf{p}_3| dm_{12} d\Omega_1^* d\Omega_3 , \qquad (43.19)$$

where $(|p_1^*|, \Omega_1^*)$ is the momentum of particle 1 in the rest frame of 1 and 2, and Ω_3 is the angle of particle 3 in the rest frame of the decaying particle. $|p_1^*|$ and $|p_3|$ are given by

$$|\mathbf{p}_{1}^{*}| = \frac{\left[\left(m_{12}^{2} - (m_{1} + m_{2})^{2}\right)\left(m_{12}^{2} - (m_{1} - m_{2})^{2}\right)\right]^{1/2}}{2m_{12}}, \quad (43.20a)$$

$$|\mathbf{p}_3| = \frac{\left[\left(M^2 - (m_{12} + m_3)^2 \right) \left(M^2 - (m_{12} - m_3)^2 \right) \right]^{1/2}}{2M} \ . \tag{43.20b}$$

[Compare with Eq. (43.16).]

If the decaying particle is a scalar or we average over its spin states, then integration over the angles in Eq. (43.18) gives

$$d\Gamma = \frac{1}{(2\pi)^3} \frac{1}{8M} |\mathcal{M}|^2 dE_1 dE_2$$
$$= \frac{1}{(2\pi)^3} \frac{1}{32M^3} |\mathcal{M}|^2 dm_{12}^2 dm_{23}^2 . \tag{43.21}$$

This is the standard form for the Dalitz plot.

43.4.3.1. Dalitz plot: For a given value of m_{12}^2 , the range of m_{23}^2 is determined by its values when p_2 is parallel or antiparallel to p_3 :

$$(m_{23}^2)_{\rm max} =$$

$$(E_2^* + E_3^*)^2 - \left(\sqrt{E_2^{*2} - m_2^2} - \sqrt{E_3^{*2} - m_3^2}\right)^2 , (43.22a)$$

$$(m_{23}^2)_{\min} =$$

$$(m_{23}^2)_{\min} = (E_2^* + E_3^*)^2 - \left(\sqrt{E_2^{*2} - m_2^2} + \sqrt{E_3^{*2} - m_3^2}\right)^2 . \tag{43.22b}$$

Here $E_2^* = (m_{12}^2 - m_1^2 + m_2^2)/2m_{12}$ and $E_3^* = (M^2 - m_{12}^2 - m_3^2)/2m_{12}$ are the energies of particles 2 and 3 in the m_{12} rest frame. The scatter plot in m_{12}^2 and m_{23}^2 is called a Dalitz plot. If $|\mathcal{M}|^2$ is constant, the allowed region of the plot will be uniformly populated with events [see Eq. (43.21)]. A nonuniformity in the plot gives immediate information on $|\mathcal{M}|^2$. For example, in the case of $D \to K\pi\pi$, bands appear when $m_{(K\pi)}=m_{K^*(892)}$, reflecting the appearance of the decay chain $D\to K^*(892)\pi\to K\pi\pi$.

43.4.4. Kinematic limits:

43.4.4.1. Three-body decays: In a three-body decay (Fig. 43.2) the maximum of $|p_3|$, [given by Eq. (43.20)], is achieved when $m_{12} = m_1 + m_2$, i.e., particles 1 and 2 have the same vector velocity in the rest frame of the decaying particle. If, in addition, $m_3 > m_1, m_2$, then $|\boldsymbol{p}_3|_{\max} > |\boldsymbol{p}_1|_{\max}$, $|\boldsymbol{p}_2|_{\max}$. The distribution of m_{12} values possesses an end-point or maximum value at $m_{12} = M - m_3$. This can be used to constrain the mass difference of a parent particle and one invisible decay product.

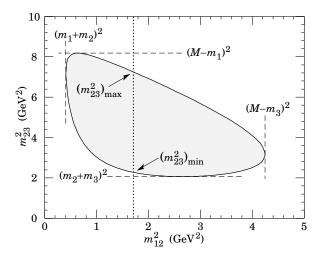

Figure 43.3: Dalitz plot for a three-body final state. In this example, the state is $\pi^+ \overline{K}{}^0 p$ at 3 GeV. Four-momentum conservation restricts events to the shaded region.

43.4.4.2. Sequential two-body decays:

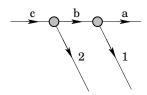

Figure 43.4: Particles participating in sequential two-body decay chain. Particles labeled 1 and 2 are visible while the particle terminating the chain (a) is invisible.

When a heavy particle initiates a sequential chain of two-body decays terminating in an invisible particle, constraints on the masses of the states participating in the chain can be obtained from end-points and thresholds in invariant mass distributions of the aggregated decay products. For the two-step decay chain depicted in Fig. 43.4 the invariant mass distribution of the two visible particles possesses an end-point given by:

$$(m_{12}^{\text{max}})^2 = \frac{(m_{\rm c}^2 - m_{\rm b}^2)(m_{\rm b}^2 - m_{\rm a}^2)}{m_{\rm b}^2} ,$$
 (43.23)

provided particles 1 and 2 are massless. If visible particle 1 has non-zero mass m_1 then Eq. (43.23) is replaced by

$$(m_{12}^{\text{max}})^2 = m_1^2 + \frac{(m_c^2 - m_b^2)}{2m_b^2} \times$$

$$\left(m_1^2 + m_{\rm b}^2 - m_{\rm a}^2 + \sqrt{(-m_1^2 + m_{\rm b}^2 - m_{\rm a}^2)^2 - 4m_1^2 m_{\rm a}^2}\right). \tag{43.24}$$

See Refs. 2 and 3 for other cases.

43.4.5. Multibody decays: The above results may be generalized to final states containing any number of particles by combining some of the particles into "effective particles" and treating the final states as 2 or 3 "effective particle" states. Thus, if $p_{ijk...} = p_i + p_j + p_k + \ldots$,

$$m_{ijk...} = \sqrt{p^2_{ijk...}} , \qquad (43.25)$$

and $m_{ijk...}$ may be used in place of e.g., m_{12} in the relations in Sec. 43.4.3 or Sec. 43.4.4 above.

43.5. Cross sections

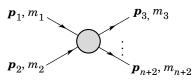

Figure 43.5: Definitions of variables for production of an n-body final state.

The differential cross section is given by

$$d\sigma = \frac{(2\pi)^4 |\mathcal{M}|^2}{4\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2}} \times d\Phi_n(p_1 + p_2; p_3, \dots, p_{n+2}) . \tag{43.26}$$

[See Eq. (43.11).] In the rest frame of $m_2(lab)$,

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = m_2 p_{1 \, \text{lab}} ; \qquad (43.27a)$$

while in the center-of-mass frame

$$\sqrt{(p_1 \cdot p_2)^2 - m_1^2 m_2^2} = p_{1\text{cm}} \sqrt{s} \ . \tag{43.27b}$$

43.5.1. Two-body reactions:

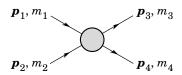

Figure 43.6: Definitions of variables for a two-body final state.

Two particles of momenta p_1 and p_2 and masses m_1 and m_2 scatter to particles of momenta p_3 and p_4 and masses m_3 and m_4 ; the Lorentz-invariant Mandelstam variables are defined by

$$s = (p_1 + p_2)^2 = (p_3 + p_4)^2$$

= $m_1^2 + 2E_1E_2 - 2\mathbf{p}_1 \cdot \mathbf{p}_2 + m_2^2$, (43.28)
$$t = (p_1 - p_3)^2 = (p_2 - p_4)^2$$

$$t - (p_1 - p_3) - (p_2 - p_4)$$

$$= m_1^2 - 2E_1E_3 + 2\mathbf{p}_1 \cdot \mathbf{p}_3 + m_3^2 , \qquad (43.29)$$

$$u = (p_1 - p_4)^2 = (p_2 - p_3)^2$$

= $m_1^2 - 2E_1E_4 + 2\mathbf{p}_1 \cdot \mathbf{p}_4 + m_4^2$, (43.30)

and they satisfy

$$s + t + u = m_1^2 + m_2^2 + m_3^2 + m_4^2$$
 (43.31)

The two-body cross section may be written as

$$\frac{d\sigma}{dt} = \frac{1}{64\pi s} \frac{1}{|\mathbf{p}_{1cm}|^2} |\mathcal{M}|^2.$$
 (43.32)

In the center-of-mass frame

$$t = (E_{1\text{cm}} - E_{3\text{cm}})^2 - (p_{1\text{cm}} - p_{3\text{cm}})^2 - 4p_{1\text{cm}} p_{3\text{cm}} \sin^2(\theta_{\text{cm}}/2)$$
$$= t_0 - 4p_{1\text{cm}} p_{3\text{cm}} \sin^2(\theta_{\text{cm}}/2) , \qquad (43.33)$$

where $\theta_{\rm cm}$ is the angle between particle 1 and 3. The limiting values t_0 ($\theta_{\rm cm}=0$) and t_1 ($\theta_{\rm cm}=\pi$) for $2\to 2$ scattering are

$$t_0(t_1) = \left[\frac{m_1^2 - m_3^2 - m_2^2 + m_4^2}{2\sqrt{s}}\right]^2 - (p_{1 \text{ cm}} \mp p_{3 \text{ cm}})^2 . \tag{43.34}$$

In the literature the notation t_{\min} (t_{\max}) for t_0 (t_1) is sometimes used, which should be discouraged since $t_0 > t_1$. The center-of-mass energies and momenta of the incoming particles are

$$E_{1{\rm cm}} = \frac{s + m_1^2 - m_2^2}{2\sqrt{s}} \ , \qquad E_{2{\rm cm}} = \frac{s + m_2^2 - m_1^2}{2\sqrt{s}} \ , \eqno(43.35)$$

For $E_{3\mathrm{cm}}$ and $E_{4\mathrm{cm}}$, change m_1 to m_3 and m_2 to m_4 . Then

$$p_{i\,{\rm cm}} = \sqrt{E_{i\,{\rm cm}}^2 - m_i^2}$$
 and $p_{1{\rm cm}} = \frac{p_{1\,{\rm lab}} \, m_2}{\sqrt{s}}$. (43.36)

Here the subscript lab refers to the frame where particle 2 is at rest. [For other relations see Eqs. (43.2)–(43.4).]

43.5.2. *Inclusive reactions*: Choose some direction (usually the beam direction) for the z-axis; then the energy and momentum of a particle can be written as

$$E = m_T \cosh y \; , \; p_x \; , \; p_y \; , \; p_z = m_T \sinh y \; , \eqno(43.37)$$

where m_T , conventionally called the 'transverse mass', is given by

$$m_T^2 = m^2 + p_x^2 + p_y^2 \ . (43.38)$$

and the rapidity y is defined by

$$y = \frac{1}{2} \ln \left(\frac{E + p_z}{E - p_z} \right)$$

$$= \ln \left(\frac{E + p_z}{m_T} \right) = \tanh^{-1} \left(\frac{p_z}{E} \right) . \tag{43.39}$$

Note that the definition of the transverse mass in Eq. (43.38) differs from that used by experimentalists at hadron colliders (see Sec. 43.6.1 below). Under a boost in the z-direction to a frame with velocity β , $y \to y - \tanh^{-1}\beta$. Hence the shape of the rapidity distribution dN/dy is invariant, as are differences in rapidity. The invariant cross section may also be rewritten

$$E \frac{d^3 \sigma}{d^3 p} = \frac{d^3 \sigma}{d \phi \, dy \, p_T dp_T} \Longrightarrow \frac{d^2 \sigma}{\pi \, dy \, d(p_T^2)} \; . \eqno(43.40)$$

The second form is obtained using the identity $dy/dp_z = 1/E$, and the third form represents the average over ϕ .

Feynman's x variable is given by

$$x = \frac{p_z}{p_{z\,\mathrm{max}}} \approx \frac{E + p_z}{(E + p_z)_{\mathrm{max}}} \quad (p_T \ll |p_z|) \ . \tag{43.41} \label{eq:43.41}$$

In the c.m. frame.

$$x \approx \frac{2p_{z\,\mathrm{cm}}}{\sqrt{s}} = \frac{2m_T\,\mathrm{sinh}\,y_\mathrm{cm}}{\sqrt{s}} \tag{43.42}$$

and

$$= (y_{\rm cm})_{\rm max} = \ln(\sqrt{s}/m)$$
 (43.43)

The invariant mass M of the two-particle system described in Sec. 43.4.2 can be written in terms of these variables as

$$M^{2} = m_{1}^{2} + m_{2}^{2} + 2[E_{T}(1)E_{T}(2)\cosh\Delta y - \mathbf{p}_{T}(1)\cdot\mathbf{p}_{T}(2)], \quad (43.44)$$

where

$$E_T(i) = \sqrt{|\mathbf{p}_T(i)|^2 + m_i^2}$$
, (43.45)

and $p_T(i)$ denotes the transverse momentum vector of particle i.

For $p \gg m$, the rapidity [Eq. (43.39)] may be expanded to obtain

$$y = \frac{1}{2} \ln \frac{\cos^2(\theta/2) + m^2/4p^2 + \dots}{\sin^2(\theta/2) + m^2/4p^2 + \dots}$$

$$\approx -\ln \tan(\theta/2) \equiv n$$
 (43.46)

where $\cos\theta=p_z/p$. The pseudorapidity η defined by the second line is approximately equal to the rapidity y for $p\gg m$ and $\theta\gg 1/\gamma$, and in any case can be measured when the mass and momentum of the particle are unknown. From the definition one can obtain the identities

$$\sinh \eta = \cot \theta$$
, $\cosh \eta = 1/\sin \theta$, $\tanh \eta = \cos \theta$. (43.47)

43.5.3. *Partial waves*: The amplitude in the center of mass for elastic scattering of spinless particles may be expanded in Legendre polynomials

$$f(k,\theta) = \frac{1}{k} \sum_{\ell} (2\ell + 1) a_{\ell} P_{\ell}(\cos \theta) ,$$
 (43.48)

where k is the c.m. momentum, θ is the c.m. scattering angle, $a_{\ell} = (\eta_{\ell}e^{2i\delta_{\ell}} - 1)/2i$, $0 \leq \eta_{\ell} \leq 1$, and δ_{ℓ} is the phase shift of the ℓ^{th} partial wave. For purely elastic scattering, $\eta_{\ell} = 1$. The differential cross section is

$$\frac{d\sigma}{d\Omega} = |f(k,\theta)|^2 . \tag{43.49}$$

The optical theorem states that

$$\sigma_{\text{tot}} = \frac{4\pi}{k} \text{Im} f(k, 0) , \qquad (43.50)$$

and the cross section in the ℓ^{th} partial wave is therefore bounded:

$$\sigma_{\ell} = \frac{4\pi}{k^2} (2\ell + 1)|a_{\ell}|^2 \le \frac{4\pi (2\ell + 1)}{k^2} . \tag{43.51}$$

The evolution with energy of a partial-wave amplitude a_{ℓ} can be displayed as a trajectory in an Argand plot, as shown in Fig. 43.7.

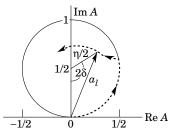

Figure 43.7: Argand plot showing a partial-wave amplitude a_{ℓ} as a function of energy. The amplitude leaves the unitary circle where inelasticity sets in $(\eta_{\ell} < 1)$.

The usual Lorentz-invariant matrix element \mathcal{M} (see Sec. 43.3 above) for the elastic process is related to $f(k, \theta)$ by

$$\mathcal{M} = -8\pi\sqrt{s} f(k,\theta) , \qquad (43.52)$$

so

$$\sigma_{\text{tot}} = -\frac{1}{2p_{\text{lab}} m_2} \text{Im} \mathcal{M}(t=0) ,$$
 (43.53)

where s and t are the center-of-mass energy squared and momentum transfer squared, respectively (see Sec. 43.4.1).

43.5.3.1. Resonances: The Breit-Wigner (nonrelativistic) form for an elastic amplitude a_ℓ with a resonance at c.m. energy E_R , elastic width $\Gamma_{\rm el}$, and total width $\Gamma_{\rm tot}$ is

$$a_{\ell} = \frac{\Gamma_{\rm el}/2}{E_R - E - i\Gamma_{\rm tot}/2} , \qquad (43.54)$$

where E is the c.m. energy. As shown in Fig. 43.8, in the absence of background the elastic amplitude traces a counterclockwise circle with center $ix_{\rm el}/2$ and radius $x_{\rm el}/2$, where the elasticity $x_{\rm el}=\Gamma_{\rm el}/\Gamma_{\rm tot}$. The amplitude has a pole at $E=E_R-i\Gamma_{\rm tot}/2$.

The spin-averaged Breit-Wigner cross section for a spin-J resonance produced in the collision of particles of spin S_1 and S_2 is

$$\sigma_{BW}(E) = \frac{(2J+1)}{(2S_1+1)(2S_2+1)} \frac{\pi}{k^2} \frac{B_{\rm in} B_{\rm out} \Gamma_{\rm tot}^2}{(E-E_R)^2 + \Gamma_{\rm tot}^2/4} , \quad (43.55)$$

where k is the c.m. momentum, E is the c.m. energy, and $B_{\rm in}$ and $B_{\rm out}$ are the branching fractions of the resonance into the entrance and exit channels. The 2S+1 factors are the multiplicities of the incident spin states, and are replaced by 2 for photons. This expression is valid only for an isolated state. If the width is not small, $\Gamma_{\rm tot}$ cannot be treated as a constant independent of E. There are many other forms for σ_{BW} , all of which are equivalent to the one given here in the narrow-width case. Some of these forms may be more appropriate if the resonance is broad.

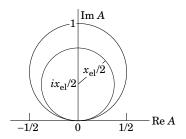

Figure 43.8: Argand plot for a resonance.

The relativistic Breit-Wigner form corresponding to Eq. (43.54) is:

$$a_{\ell} = \frac{-m\Gamma_{\rm el}}{s - m^2 + im\Gamma_{\rm tot}} \ . \tag{43.56}$$

A better form incorporates the known kinematic dependences, replacing $m\Gamma_{\rm tot}$ by $\sqrt{s}\,\Gamma_{\rm tot}(s)$, where $\Gamma_{\rm tot}(s)$ is the width the resonance particle would have if its mass were \sqrt{s} , and correspondingly $m\Gamma_{\rm el}$ by $\sqrt{s}\,\Gamma_{\rm el}(s)$ where $\Gamma_{\rm el}(s)$ is the partial width in the incident channel for a mass \sqrt{s} :

$$a_{\ell} = \frac{-\sqrt{s}\,\Gamma_{\rm el}(s)}{s - m^2 + i\sqrt{s}\,\Gamma_{\rm tot}(s)} \ . \tag{43.57}$$

For the Z boson, all the decays are to particles whose masses are small enough to be ignored, so on dimensional grounds $\Gamma_{\rm tot}(s)=\sqrt{s}\,\Gamma_0/m_Z$, where Γ_0 defines the width of the Z, and $\Gamma_{\rm el}(s)/\Gamma_{\rm tot}(s)$ is constant. A full treatment of the line shape requires consideration of dynamics, not just kinematics. For the Z this is done by calculating the radiative corrections in the Standard Model.

43.6. Transverse variables

At hadron colliders, a significant and unknown proportion of the energy of the incoming hadrons in each event escapes down the beam-pipe. Consequently if invisible particles are created in the final state, their net momentum can only be constrained in the plane transverse to the beam direction. Defining the z-axis as the beam direction, this net momentum is equal to the missing transverse energy vector

$$\boldsymbol{E}_{T}^{\text{miss}} = -\sum_{i} \boldsymbol{p}_{T}(i) , \qquad (43.58)$$

where the sum runs over the transverse momenta of all visible final state particles.

43.6.1. Single production with semi-invisible final state:

Consider a single heavy particle of mass M produced in association with visible particles which decays as in Fig. 43.1 to two particles, of which one (labeled particle 1) is invisible. The mass of the parent particle can be constrained with the quantity M_T defined by

$$\begin{split} M_T^2 &\equiv [E_T(1) + E_T(2)]^2 - [\boldsymbol{p}_T(1) + \boldsymbol{p}_T(2)]^2 \\ &= m_1^2 + m_2^2 + 2[E_T(1)E_T(2) - \boldsymbol{p}_T(1) \cdot \boldsymbol{p}_T(2)] \;, \quad (43.59) \end{split}$$

where

$$\boldsymbol{p}_T(1) = \boldsymbol{E}_T^{\text{miss}} \,. \tag{43.60}$$

This quantity is called the 'transverse mass' by hadron collider experimentalists but it should be noted that it is quite different from that used in the description of inclusive reactions [Eq. (43.38)]. The distribution of event M_T values possesses an end-point at $M_T^{\rm max}=M$. If $m_1=m_2=0$ then

$$M_T^2 = 2|\mathbf{p}_T(1)||\mathbf{p}_T(2)|(1-\cos\phi_{12})$$
, (43.61)

where ϕ_{ij} is defined as the angle between particles i and j in the transverse plane.

${\bf 43.6.2.} \quad Pair\ production\ with\ semi-invisible\ final\ states:$

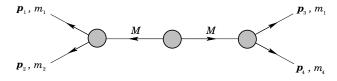

Figure 43.9: Definitions of variables for pair production of semi-invisible final states. Particles 1 and 3 are invisible while particles 2 and 4 are visible.

Consider two identical heavy particles of mass M produced such that their combined center-of-mass is at rest in the transverse plane (Fig. 43.9). Each particle decays to a final state consisting of an invisible particle of fixed mass m_1 together with an additional visible particle. M and m_1 can be constrained with the variables M_{T2} and M_{CT} which are defined in Refs. [4] and [5].

44. CROSS-SECTION FORMULAE FOR SPECIFIC PROCESSES

Revised October 2009 by H. Baer (University of Oklahoma) and R.N. Cahn (LBNL).

PART I: STANDARD MODEL PROCESSES

Setting aside leptoproduction (for which, see Sec. 16 of this Review), the cross sections of primary interest are those with light incident particles, e^+e^- , $\gamma\gamma$, $q\overline{q}$, gq, gg, etc., where g and q represent gluons and light quarks. The produced particles include both light particles and heavy ones - t, W, Z, and the Higgs boson H. We provide the production cross sections calculated within the Standard Model for several such processes.

44.1. Resonance Formation

Resonant cross sections are generally described by the Breit-Wigner formula (Sec. 18 of this Review).

$$\sigma(E) = \frac{2J+1}{(2S_1+1)(2S_2+1)} \frac{4\pi}{k^2} \left[\frac{\Gamma^2/4}{(E-E_0)^2 + \Gamma^2/4} \right] B_{in} B_{out}, \quad (44.1)$$

where E is the c.m. energy, J is the spin of the resonance, and the number of polarization states of the two incident particles are $2S_1+1$ and $2S_2+1$. The c.m. momentum in the initial state is k, E_0 is the c.m. energy at the resonance, and Γ is the full width at half maximum height of the resonance. The branching fraction for the resonance into the initial-state channel is B_{in} and into the final-state channel is B_{out} . For a narrow resonance, the factor in square brackets may be replaced by $\pi\Gamma\delta(E-E_0)/2$.

44.2. Production of light particles

The production of point-like, spin-1/2 fermions in e^+e^- annihilation through a virtual photon, $e^+e^- \to \gamma^* \to f\overline{f}$, at c.m. energy squared s is given by

$$\frac{d\sigma}{d\Omega} = N_c \frac{\alpha^2}{4\epsilon} \beta \left[1 + \cos^2 \theta + (1 - \beta^2) \sin^2 \theta \right] Q_f^2 , \qquad (44.2)$$

where β is v/c for the produced fermions in the c.m., θ is the c.m. scattering angle, and Q_f is the charge of the fermion. The factor N_c is 1 for charged leptons and 3 for quarks. In the ultrarelativistic limit, $\beta \to 1$,

$$\sigma = N_c Q_f^2 \frac{4\pi\alpha^2}{3s} = N_c Q_f^2 \frac{86.8 \text{ nb}}{s \text{ (GeV}^2)}.$$
 (44.3)

The cross section for the annihilation of a $q\overline{q}$ pair into a distinct pair $q'\overline{q}'$ through a gluon is completely analogous up to color factors, with the replacement $\alpha \to \alpha_s$. Treating all quarks as massless, averaging over the colors of the initial quarks and defining $t = -s \sin^2(\theta/2)$, $u = -s \cos^2(\theta/2)$, one finds [1]

$$\frac{d\sigma}{d\Omega}(q\overline{q} \to q'\overline{q}') = \frac{\alpha_s^2}{9s} \frac{t^2 + u^2}{s^2} \ . \tag{44.4}$$

Crossing symmetry gives

$$\frac{d\sigma}{d\Omega}(qq' \rightarrow qq') = \frac{\alpha_s^2}{\alpha_s} \frac{s^2 + u^2}{t^2}$$
. (44.5)

If the quarks q and q' are identical, we have

$$\frac{d\sigma}{d\Omega}(q\overline{q} \to q\overline{q}) = \frac{\alpha_s^2}{9s} \left[\frac{t^2 + u^2}{s^2} + \frac{s^2 + u^2}{t^2} - \frac{2u^2}{3st} \right] , \qquad (44.6)$$

and by crossing

$$\frac{d\sigma}{d\Omega}(qq\rightarrow qq) = \frac{\alpha_s^2}{9s} \left[\frac{t^2+s^2}{u^2} + \frac{s^2+u^2}{t^2} - \frac{2s^2}{3ut} \right]. \tag{44.7} \label{eq:44.7}$$

Annihilation of e^+e^- into $\gamma\gamma$ has the cross section

$$\frac{d\sigma}{d\Omega}(e^+e^- \to \gamma\gamma) = \frac{\alpha^2}{2s} \frac{u^2 + t^2}{tu} \ . \tag{44.8}$$

The related QCD process also has a triple-gluon coupling. The cross section is

$$\frac{d\sigma}{d\Omega}(q\overline{q} \to gg) = \frac{8\alpha_s^2}{27s}(t^2 + u^2)\left(\frac{1}{tu} - \frac{9}{4s^2}\right). \tag{44.9}$$

The crossed reactions are

$$\frac{d\sigma}{d\Omega}(qg\rightarrow qg) = \frac{\alpha_s^2}{9s}(s^2+u^2)(-\frac{1}{su}+\frac{9}{4t^2}) \eqno(44.10)$$

and

$$\frac{d\sigma}{d\Omega}(gg\to q\overline{q}) = \frac{\alpha_s^2}{24s}(t^2+u^2)(\frac{1}{tu}-\frac{9}{4s^2})\;. \eqno(44.11)$$

Finally,

$$\frac{d\sigma}{d\Omega}(gg\to gg) = \frac{9\alpha_s^2}{8s}(3-\frac{ut}{s^2}-\frac{su}{t^2}-\frac{st}{u^2})\ . \eqno(44.12)$$

Lepton-quark scattering is analogous (neglecting Z exchange)

$$\frac{d\sigma}{d\Omega}(eq \to eq) = \frac{\alpha^2}{2s}e_q^2 \frac{s^2 + u^2}{t^2} \ . \tag{44.13}$$

where e_q is the charge of the quark. For neutrino scattering with the four-Fermi interaction

$$\frac{d\sigma}{d\Omega}(\nu d \to \ell^- u) = \frac{G_F^2 s}{4\pi^2} , \qquad (44.14)$$

where the Cabibbo angle suppression is ignored. Similarly

$$\frac{d\sigma}{d\Omega}(\nu \overline{u} \to \ell^+ \overline{d}) = \frac{G_F^2 s}{4\pi^2} \frac{(1 + \cos \theta)^2}{4} \ . \tag{44.15}$$

To obtain the formulae for deep inelastic scattering (presented in more detail in Section 16) we consider quarks of type i carrying a fraction $x=Q^2/(2M\nu)$ of the nucleon's energy, where $\nu=E-E'$ is the energy lost by the lepton in the nucleon rest frame. With $y=\nu/E$ we have the correspondences

$$1 + \cos \theta \rightarrow 2(1 - y)$$
,
 $d\Omega_{cm} \rightarrow 4\pi f_i(x) dx dy$, (44.16)

where the latter incorporates the quark distribution, $f_i(x)$. In this way we find

$$\frac{d\sigma}{dx\,dy}(eN \to eX) = \frac{4\pi\alpha^2 xs}{Q^4} \frac{1}{2} \left[1 + (1-y)^2 \right] \times \left[\frac{4}{9} (u(x) + \overline{u}(x) + \ldots) + \frac{1}{9} (d(x) + \overline{d}(x) + \ldots) \right] (44.17)$$

where now s=2ME is the cm energy squared for the electron-nucleon collision and we have suppressed contributions from higher mass quarks.

Similarly,

$$\frac{d\sigma}{dx\,du}(\nu N \to \ell^{-}X) = \frac{G_F^2 x s}{\pi} [(d(x) + \ldots) + (1-y)^2(\overline{u}(x) + \ldots)] \quad (44.18)$$

and

$$\frac{d\sigma}{dx\,dy}(\overline{\nu}N \to \ell^+ X) = \frac{G_F^2 x s}{\pi} [(\overline{d}(x) + \ldots) + (1 - y)^2 (u(x) + \ldots)] . \quad (44.19)$$

Quasi-elastic neutrino scattering $(\nu_{\mu}n \to \mu^{-}p, \overline{\nu}_{\mu}p \to \mu^{+}n)$ is directly related to the crossed reaction, neutron decay. The formula for the differential cross section is presented, for example, in N.J. Baker *et al.*, Phys. Rev. **D23**, 2499 (1981).

44.3. Hadroproduction of heavy quarks

For hadroproduction of heavy quarks $Q=c,\ b,\ t,$ it is important to include mass effects in the formulae. For $q\bar q\to Q\bar Q$, one has

$$\frac{d\sigma}{d\Omega}(q\bar{q}\to Q\bar{Q}) = \frac{\alpha_s^2}{9s^3} \left[(m_Q^2 - t)^2 + (m_Q^2 - u)^2 + 2m_Q^2 s \right], \quad (44.20)$$

while for $gg \to Q\bar{Q}$ one has

$$\begin{split} \frac{d\sigma}{d\Omega}(gg \to Q\bar{Q}) &= \frac{\alpha_s^2}{32s} \left[\frac{6}{s^2} (m_Q^2 - t)(m_Q^2 - u) - \frac{m_Q^2(s - 4m_Q^2)}{3(m_Q^2 - t)(m_Q^2 - u)} + \right. \\ &\qquad \qquad \left. \frac{4}{3} \frac{(m_Q^2 - t)(m_Q^2 - u) - 2m_Q^2(m_Q^2 + t)}{(m_Q^2 - t)^2} \right. \\ &\qquad \qquad \left. + \frac{4}{3} \frac{(m_Q^2 - t)(m_Q^2 - u) - 2m_Q^2(m_Q^2 + u)}{(m_Q^2 - u)^2} \right. \\ &\qquad \qquad \left. - \left[.3 \frac{(m_Q^2 - t)(m_Q^2 - u) + m_Q^2(u - t)}{s(m_Q^2 - t)} \right. \\ &\qquad \qquad \left. - 3 \frac{(m_Q^2 - t)(m_Q^2 - u) + m_Q^2(t - u)}{s(m_Q^2 - u)} \right]. \end{split} \tag{44.21}$$

44.4. Production of Weak Gauge Bosons

44.4.1. W and Z resonant production:

Resonant production of a single W or Z is governed by the partial widths

$$\Gamma(W \to \ell_i \overline{\nu}_i) = \frac{\sqrt{2} G_F m_W^3}{12\pi}$$

$$\Gamma(W \to q_i \overline{q}_j) = 3 \frac{\sqrt{2} G_F |V_{ij}|^2 m_W^3}{12\pi}$$

$$\Gamma(Z \to f \overline{f}) = N_c \frac{\sqrt{2} G_F m_Z^3}{6\pi}$$

$$\times \left[(T_3 - Q_f \sin^2 \theta_W)^2 + (Q_f \sin \theta_W)^2 \right] . (44.24)$$

The weak mixing angle is θ_W . The CKM matrix elements are indicated by V_{ij} and N_c is 3 for $q\overline{q}$ final states and 1 for leptonic final states.

The full differential cross section for $f_i\overline{f}_j\to (W,Z)\to f_{i'}\overline{f}_{j'}$ is given by

$$\frac{d\sigma}{d\Omega} = \frac{N_c^f}{N_c^i} \cdot \frac{1}{256\pi^2 s} \cdot \frac{s^2}{(s - M^2)^2 + s\Gamma^2}
\times \left[(L^2 + R^2)(L'^2 + R'^2)(1 + \cos^2 \theta) \right]
+ (L^2 - R^2)(L'^2 - R'^2)2 \cos \theta$$
(44.25)

where M is the mass of the W or Z. The couplings for the W are $L=(8G_Fm_W^2/\sqrt{2})^{1/2}V_{ij}/\sqrt{2}; R=0$ where V_{ij} is the corresponding CKM matrix element, with an analogous expression for L' and R'. For Z, the couplings are $L=(8G_Fm_Z^2/\sqrt{2})^{1/2}(T_3-\sin^2\theta_WQ); R=-(8G_Fm_Z^2/\sqrt{2})^{1/2}\sin^2\theta_WQ$, where T_3 is the weak isospin of the initial left-handed fermion and Q is the initial fermion's electric charge. The expressions for L' and R' are analogous. The color factors $N_c^{i,f}$ are 3 for initial or final quarks and 1 for initial or final leptons.

44.4.2. Production of pairs of weak gauge bosons:

The cross section for $f\overline{f} \to W^+W^-$ is given in term of the couplings of the left-handed and right-handed fermion $f,\ \ell=2(T_3-Qx_W),\ r=-2Qx_W,$ where T_3 is the third component of weak isospin for the left-handed $f,\ Q$ is its electric charge (in units of the proton charge), and $x_W=\sin^2\theta_W$:

$$\begin{split} \frac{d\sigma}{dt} &= \frac{2\pi\alpha^2}{N_c s^2} \Biggl\{ \Biggl[\Biggl(Q + \frac{\ell + r}{4x_W} \frac{s}{s - m_Z^2} \Biggr)^2 + \Biggl(\frac{\ell - r}{4x_W} \frac{s}{s - m_Z^2} \Biggr)^2 \Biggr] A(s, t, u) \\ &+ \frac{1}{2x_W} \Biggl(Q + \frac{\ell}{2x_W} \frac{s}{s - m_Z^2} \Biggr) \left(\Theta(-Q) I(s, t, u) - \Theta(Q) I(s, u, t) \right) \\ &+ \frac{1}{8x_W^2} \left(\Theta(-Q) E(s, t, u) + \Theta(Q) E(s, u, t) \right) \Biggr\} \,, \end{split}$$
(44.26)

where $\Theta(x)$ is 1 for x > 0 and 0 for x < 0, and where

$$A(s,t,u) = \left(\frac{tu}{m_W^4} - 1\right) \left(\frac{1}{4} - \frac{m_W^2}{s} + 3\frac{m_W^4}{s^2}\right) + \frac{s}{m_W^2} - 4,$$

$$I(s,t,u) = \left(\frac{tu}{m_W^4} - 1\right) \left(\frac{1}{4} - \frac{m_W^2}{2s} - \frac{m_W^4}{st}\right) + \frac{s}{m_W^2} - 2 + 2\frac{m_W^2}{t},$$

$$E(s,t,u) = \left(\frac{tu}{m_W^4} - 1\right) \left(\frac{1}{4} + \frac{m_W^4}{t^2}\right) + \frac{s}{m_W^2},$$

$$(44.27)$$

and s,t,u are the usual Mandelstam variables with $s=(p_f+p_{\overline{f}})^2,t=(p_f-p_{W^-})^2,u=(p_f-p_{W^+})^2$. The factor N_c is 3 for quarks and 1 for leptons.

The analogous cross-section for $q_i\overline{q}_j\to W^\pm Z^0$ is

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2 |V_{ij}|^2}{6s^2 x_W^2} \left\{ \left(\frac{1}{s - m_W^2} \right)^2 \left[\left(\frac{9 - 8x_W}{4} \right) \left(ut - m_W^2 m_Z^2 \right) \right. \right. \\
+ \left. \left(8x_W - 6 \right) s \left(m_W^2 + m_Z^2 \right) \right] \\
+ \left[\frac{ut - m_W^2 m_Z^2 - s(m_W^2 + m_Z^2)}{s - m_W^2} \right] \left[\frac{\ell_j}{t} - \frac{\ell_i}{u} \right] \\
+ \left. \frac{ut - m_W^2 m_Z^2}{4(1 - x_W)} \left[\frac{\ell_j^2}{t^2} + \frac{\ell_i^2}{u^2} \right] + \frac{s(m_W^2 + m_Z^2)}{2(1 - x_W)} \frac{\ell_i \ell_j}{tu} \right\}, \quad (44.28)$$

where ℓ_i and ℓ_j are the couplings of the left-handed q_i and q_j as defined above. The CKM matrix element between q_i and q_j is V_{ij} .

The cross section for $q_i \overline{q}_i \to Z^0 Z^0$ is

$$\frac{d\sigma}{dt} = \frac{\pi\alpha^2}{96} \frac{\ell_i^4 + r_i^4}{x_W^2 (1 - x_W^2)^2 s^2} \left[\frac{t}{u} + \frac{u}{t} + \frac{4m_Z^2 s}{tu} - m_Z^4 \left(\frac{1}{t^2} + \frac{1}{u^2} \right) \right]. \tag{44.29}$$

44.5. Production of Higgs Bosons

44.5.1. Resonant Production:

The Higgs boson of the Standard Model can be produced resonantly in the collisions of quarks, leptons, W or Z bosons, gluons, or photons. The production cross section is thus controlled by the partial width of the Higgs boson into the entrance channel and its total width. The branching fractions for the Standard Model Higgs boson are shown in Fig. 1 of the "Searches for Higgs bosons" review in the Particle Listings section, as a function of the Higgs boson mass. The partial widths are given by the relations

$$\Gamma(H \to f\overline{f}) = \frac{G_F m_f^2 m_H N_c}{4\pi\sqrt{2}} \left(1 - 4m_f^2/m_H^2\right)^{3/2}, (44.30)$$

$$\Gamma(H \to W^+W^-) = \frac{G_F m_H^3 \beta_W}{32\pi\sqrt{2}} \left(4 - 4a_W + 3a_W^2\right), (44.31)$$

$$\Gamma(H \to ZZ) = \frac{G_F m_H^3 \beta_Z}{64\pi\sqrt{2}} \left(4 - 4a_Z + 3a_Z^2 \right),$$
 (44.32)

where N_c is 3 for quarks and 1 for leptons and where $a_W = 1 - \beta_W^2 = 4m_W^2/m_H^2$ and $a_Z = 1 - \beta_Z^2 = 4m_Z^2/m_H^2$. The decay to two gluons proceeds through quark loops, with the t quark dominating [2]. Explicitly,

$$\Gamma(H \to gg) = \frac{\alpha_s^2 G_F m_H^3}{36\pi^3 \sqrt{2}} \left| \sum_q I(m_q^2/m_H^2) \right|^2, \tag{44.33}$$

where I(z) is complex for z < 1/4. For $z < 2 \times 10^{-3}$, |I(z)| is small so the light quarks contribute negligibly. For $m_H < 2m_t$, z > 1/4 and

$$I(z) = 3 \left[2z + 2z(1 - 4z) \left(\sin^{-1} \frac{1}{2\sqrt{z}} \right)^2 \right], \tag{44.34}$$

which has the limit $I(z) \to 1$ as $z \to \infty$.

44.5.2. Higgs Boson Production in W^* and Z^* decay:

The Standard Model Higgs boson can be produced in the decay of a virtual W or Z ("Higgstrahlung") [3,4]: In particular, if k is the c.m. momentum of the Higgs boson,

$$\sigma(q_i \overline{q}_j \to WH) = \frac{\pi \alpha^2 |V_{ij}|^2}{36 \sin^4 \theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_W^2}{(s - m_W^2)^2}$$
(44.35)

$$\sigma(f\overline{f} \to ZH) = \frac{2\pi\alpha^2(\ell_f^2 + r_f^2)}{48N_c \sin^4 \theta_W \cos^4 \theta_W} \frac{2k}{\sqrt{s}} \frac{k^2 + 3m_Z^2}{(s - m_Z^2)^2}, (44.36)$$

where ℓ and r are defined as above.

44.5.3. W and Z Fusion:

Just as high-energy electrons can be regarded as sources of virtual photon beams, at very high energies they are sources of virtual W and Z beams. For Higgs boson production, it is the longitudinal components of the Ws and Zs that are important [5]. The distribution of longitudinal Ws carrying a fraction y of the electron's energy is [6]

$$f(y) = \frac{g^2}{16\pi^2} \frac{1-y}{y},\tag{44.37}$$

where $g=e/\sin\theta_W$. In the limit $s\gg m_H\gg m_W$, the partial decay rate is $\Gamma(H\to W_LW_L)=(g^2/64\pi)(m_H^3/m_W^2)$ and in the equivalent W approximation [7]

$$\sigma(e^+e^- \to \overline{\nu}_e \nu_e H) = \frac{1}{16m_W^2} \left(\frac{\alpha}{\sin^2 \theta_W}\right)^3 \times \left[\left(1 + \frac{m_H^2}{s}\right) \log \frac{s}{m_H^2} - 2 + 2\frac{m_H^2}{s}\right]. (44.38)$$

There are significant corrections to this relation when m_H is not large compared to m_W [8]. For $m_H=150$ GeV, the estimate is too high by 51% for $\sqrt{s}=1000$ GeV, 32% too high at $\sqrt{s}=2000$ GeV, and 22% too high at $\sqrt{s}=4000$ GeV. Fusion of ZZ to make a Higgs boson can be treated similarly. Identical formulae apply for Higgs production in the collisions of quarks whose charges permit the emission of a W^+ and a W^- , except that QCD corrections and CKM matrix elements are required. Even in the absence of QCD corrections, the fine-structure constant ought to be evaluated at the scale of the collision, say m_W . All quarks contribute to the ZZ fusion process.

44.6. Inclusive hadronic reactions

One-particle inclusive cross sections $Ed^3\sigma/d^3p$ for the production of a particle of momentum p are conveniently expressed in terms of rapidity y (see above) and the momentum p_T transverse to the beam direction (in the c.m.):

$$E\frac{d^{3}\sigma}{d^{3}p} = \frac{d^{3}\sigma}{d\phi \, dy \, p_{T} dp_{T}^{2}} \, . \tag{44.39}$$

In appropriate circumstances, the cross section may be decomposed as a partonic cross section multiplied by the probabilities of finding partons of the prescribed momenta:

$$\sigma_{\text{hadronic}} = \sum_{ij} \int dx_1 \ dx_2 \ f_i(x_1) \ f_j(x_2) \ d\widehat{\sigma}_{\text{partonic}} \ , \tag{44.40}$$

The probability that a parton of type i carries a fraction of the incident particle's that lies between x_1 and $x_1 + dx_1$ is $f_i(x_1)dx_1$ and similarly for partons in the other incident particle. The partonic collision is specified by its c.m. energy squared $\hat{s} = x_1x_2s$ and the momentum transfer squared \hat{t} . The final hadronic state is more conveniently specified by the rapidities y_1, y_2 of the two jets resulting from the collision and the transverse momentum p_T . The connection between the differentials is

$$dx_1 dx_2 d\hat{t} = dy_1 dy_2 \frac{\hat{s}}{s} dp_T^2, \tag{44.41}$$

so that

$$\frac{d^{3}\sigma}{dy_{1}dy_{2}dp_{T}^{2}} = \frac{\hat{s}}{s} \left[f_{i}(x_{1})f_{j}(x_{2})\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{t},\hat{u}) + f_{i}(x_{2})f_{j}(x_{1})\frac{d\hat{\sigma}}{d\hat{t}}(\hat{s},\hat{u},\hat{t}) \right], \tag{44.42}$$

where we have taken into account the possibility that the incident parton types might arise from either incident particle. The second term should be dropped if the types are identical: i = j.

44.7. Two-photon processes

In the Weizsäcker-Williams picture, a high-energy electron beam is accompanied by a spectrum of virtual photons of energies ω and invariant-mass squared $q^2=-Q^2$, for which the photon number density is

$$dn = \frac{\alpha}{\pi} \left[1 - \frac{\omega}{E} + \frac{\omega^2}{E^2} - \frac{m_e^2 \ \omega^2}{O^2 E^2} \right] \frac{d\omega}{\omega} \frac{dQ^2}{O^2}, \tag{44.43}$$

where E is the energy of the electron beam. The cross section for $e^+e^-\to e^+e^-X$ is then [9]

$$d\sigma_{e^+e^-\to e^+e^-X}(s) = dn_1 dn_2 d\sigma_{\gamma\gamma\to X}(W^2), \tag{44.44}$$

where $W^2=m_X^2$. Integrating from the lower limit $Q^2=m_e^2\frac{\omega_i^2}{E_i(E_i-\omega_i)}$ to a maximum Q^2 gives

$$\begin{split} \sigma_{e^+e^-\to e^+e^-X}(s) &= \frac{\alpha^2}{\pi^2} \int_{z_{th}}^1 \frac{dz}{z} \\ &\times \left[\left(\ln \frac{Q_{max}^2}{z m_e^2} - 1 \right)^2 f(z) + \frac{1}{3} (\ln z)^3 \right] \sigma_{\gamma\gamma\to X}(zs), (44.45) \end{split}$$

where

$$f(z) = \left(1 + \frac{1}{2}z\right)^2 \ln(1/z) - \frac{1}{2}(1-z)(3+z). \tag{44.46}$$

The appropriate value of Q^2_{max} depends on the properties of the produced system X. For production of hadronic systems, $Q^2_{max} \approx m_\rho^2$ while for lepton-pair production, $Q^2 \approx W^2$. For production of a resonance with spin $J \neq 1$, we have

$$\begin{split} \sigma_{e^+e^-\to e^+e^-R}(s) &= (2J+1)\frac{8\alpha^2\Gamma_{R\to\gamma\gamma}}{m_R^3} \\ &\times \Bigg[f(m_R^2/s) \left(\ln\frac{m_V^2s}{m_e^2m_R^2} - 1\right)^2 - \frac{1}{3} \left(\ln\frac{s}{M_R^2}\right)^3 \Bigg], (44.47) \end{split}$$

where m_V is the mass that enters into the form factor for the $\gamma\gamma \to R$ transition, typically m_{ϱ} .

PART II: PROCESSES BEYOND THE STANDARD MODEL

44.8. Production of supersymmetric particles

In supersymmetric (SUSY) theories (see Supersymmetric Particle Searches in this *Review*), every boson has a fermionic superpartner, and every fermion has a bosonic superpartner. The minimal supersymmetric Standard Model (MSSM) is a direct supersymmetrization of the Standard Model (SM), although a second Higgs doublet is needed to avoid triangle anomalies [10]. Under *soft* SUSY breaking, superpartner masses are lifted above the SM particle masses. In weak scale SUSY, the superpartners are invoked to stabilize the weak scale under radiative corrections, so the superpartners are expected to have masses of order the TeV scale.

44.8.1. Gluino and squark production:

The superpartners of gluons are the color octet, spin $-\frac{1}{2}$ gluinos (\tilde{g}) , while each helicity component of quark flavor has a spin-0 squark partner, e.g. \tilde{q}_L and \tilde{q}_R . Third generation left- and right- squarks are expected to have large mixing, resulting in mass eigenstates \tilde{q}_1 and \tilde{q}_2 , with $m_{\tilde{q}_1} < m_{\tilde{q}_2}$ (here, q denotes any of the SM flavors of quarks and \tilde{q}_i the corresponding flavor and type (i=L,R or 1,2) of squark). Gluino pair production $(\tilde{g}\tilde{g})$ takes place via either glue-glue or quark-antiquark annihilation [11].

The subprocess cross sections are usually presented as differential distributions in the Mandelstam variables s, t and u. Note that for a $2 \to 2$ scattering subprocess $ab \to cd$, the Mandelstam variable $s = (p_a + p_b)^2 = (p_c + p_d)^2$, where p_a is the 4-momentum of particle a, and so forth. The variable $t = (p_c - p_a)^2$, where c and a are taken conventionally to be the most similar particles in the subprocess. The variable u would then be equal to $(p_d - p_a)^2$. Note that since s, t and u are squares of 4-vectors, they are invariants in any inertial reference frames

Gluino pair production at hadron colliders is described by:

$$\begin{split} \frac{d\sigma}{dt}(gg \to \tilde{g}\tilde{g}) &= \frac{9\pi\alpha_s^2}{4s^2} \left\{ \frac{2(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)}{s^2} \right. \\ &\quad + \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + t)}{(m_{\tilde{g}}^2 - t)^2} \\ &\quad + \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) - 2m_{\tilde{g}}^2(m_{\tilde{g}}^2 + u)}{(m_{\tilde{g}}^2 - u)^2} + \frac{m_{\tilde{g}}^2(s - 4m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)} \\ &\quad - \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(u - t)}{s(m_{\tilde{g}}^2 - t)} - \frac{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u) + m_{\tilde{g}}^2(t - u)}{s(m_{\tilde{g}}^2 - u)} \right\}, \end{split}$$

where α_s is the strong fine structure constant. Also

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{g}\bar{g}) = \frac{8\pi\alpha_s^2}{9s^2} \left\{ \frac{4}{3} \left(\frac{m_{\tilde{g}}^2 - t}{m_{\tilde{q}}^2 - t} \right)^2 + \frac{4}{3} \left(\frac{m_{\tilde{g}}^2 - u}{m_{\tilde{q}}^2 - u} \right)^2 + \frac{3}{3} \left[(m_{\tilde{g}}^2 - t)^2 + (m_{\tilde{g}}^2 - u)^2 + 2m_{\tilde{g}}^2 s \right] - 3 \frac{\left[(m_{\tilde{g}}^2 - t)^2 + m_{\tilde{g}}^2 s \right]}{s(m_{\tilde{q}}^2 - t)} - 3 \frac{\left[(m_{\tilde{g}}^2 - u)^2 + m_{\tilde{g}}^2 s \right]}{s(m_{\tilde{g}}^2 - u)} + \frac{1}{3} \frac{m_{\tilde{g}}^2 s}{(m_{\tilde{g}}^2 - t)(m_{\tilde{g}}^2 - u)} \right\}.$$
(44.49)

Gluinos can also be produced in association with squarks: $\tilde{g}\tilde{q}_i$ production, where \tilde{q}_i represents any of the various types (left-, right-or mixed) and flavors of squarks. The subprocess cross section is independent of whether the squark is the right-, left- or mixed type:

$$\frac{d\sigma}{dt}(gq \to \tilde{g}\tilde{q}_i) = \frac{\pi\alpha_s^2}{24s^2} \frac{\left[\frac{16}{3}(s^2 + (m_{\tilde{q}_i}^2 - u)^2) + \frac{4}{3}s(m_{\tilde{q}_i}^2 - u)\right]}{s(m_{\tilde{g}}^2 - t)(m_{\tilde{q}_i}^2 - u)^2} \times \left((m_{\tilde{g}}^2 - u)^2 + (m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)^2 + \frac{2sm_{\tilde{g}}^2(m_{\tilde{q}_i}^2 - m_{\tilde{g}}^2)}{(m_{\tilde{g}}^2 - t)} \right). \tag{44.50}$$

There are many different subprocesses for production of squark pairs. Since left- and right- squarks generally have different masses and different decay patterns, we present the differential cross section for each subprocess of \tilde{q}_i (i=L,~R or 1, 2) separately. (In early literature, the following formulae were often combined into a single equation which didn't differentiate the various squark types.) The result for $qq \to \tilde{q}_i \bar{\tilde{q}}_i$ is:

$$\begin{split} \frac{d\sigma}{dt}(gg \to \tilde{q}_i\bar{\tilde{q}}_i) &= \frac{\pi\alpha_s^2}{4s^2} \left\{ \frac{1}{3} \left(\frac{m_{\tilde{q}}^2 + t}{m_{\tilde{q}}^2 - t} \right)^2 + \frac{1}{3} \left(\frac{m_{\tilde{q}}^2 + u}{m_{\tilde{q}}^2 - u} \right)^2 \right. \\ &\quad + \frac{3}{32s^2} \left(8s(4m_{\tilde{q}}^2 - s) + 4(u - t)^2 \right) + \frac{7}{12} \\ &\quad - \frac{1}{48} \frac{(4m_{\tilde{q}}^2 - s)^2}{(m_{\tilde{q}}^2 - t)(m_{\tilde{q}}^2 - u)} \\ &\quad + \frac{3}{32} \frac{\left[(t - u)(4m_{\tilde{q}}^2 + 4t - s) - 2(m_{\tilde{q}}^2 - u)(6m_{\tilde{q}}^2 + 2t - s) \right]}{s(m_{\tilde{q}}^2 - t)} \\ &\quad + \frac{3}{32} \frac{\left[(u - t)(4m_{\tilde{q}}^2 + 4u - s) - 2(m_{\tilde{q}}^2 - t)(6m_{\tilde{q}}^2 + 2u - s) \right]}{s(m_{\tilde{q}}^2 - u)} \\ &\quad + \frac{7}{96} \frac{\left[4m_{\tilde{q}}^2 + 4t - s \right]}{m_{\tilde{q}}^2 - t} + \frac{7}{96} \frac{\left[4m_{\tilde{q}}^2 + 4u - s \right]}{m_{\tilde{q}}^2 - u} \right\}, \quad (44.51) \end{split}$$

which has an obvious $u \leftrightarrow t$ symmetry.

For $q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i$ with the same initial and final state flavors, we have

$$\begin{split} \frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i\bar{\tilde{q}}_i) &= \frac{2\pi\alpha_s^2}{9s^2} \left\{ \frac{1}{(t-m_{\tilde{g}}^2)^2} + \frac{2}{s^2} - \frac{2/3}{s(t-m_{\tilde{g}}^2)} \right\} \\ &\times \left[-st - (t-m_{\tilde{q}_i}^2)^2 \right], \end{split} \tag{44.52}$$

while if initial and final state flavors are different $(q\bar{q}\to\tilde{q}_i^{\bar{r}_i^j})$ we instead have

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{q}_i'\bar{\tilde{q}}_i') = \frac{4\pi\alpha_s^2}{9s^4} \left[-st - (t - m_{\tilde{q}_i'}^2)^2 \right]. \tag{44.53}$$

If the two initial state quarks are of different flavors, then we have

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{q}'_i) = \frac{2\pi\alpha_s^2}{9s^2} \frac{-st - (t - m_{\bar{q}_i}^2)^2}{(t - m_{\bar{q}}^2)^2}.$$
 (44.54)

If the initial quarks are of different flavor and final state squarks are of different type $(i \neq j)$ then

$$\frac{d\sigma}{dt}(q\bar{q}' \to \tilde{q}_i\bar{q}'_j) = \frac{2\pi\alpha_s^2}{9s^2} \frac{m_{\tilde{g}}^2 s}{(t - m_{\tilde{g}}^2)^2}.$$
 (44.55)

For same-flavor initial state quarks, but final state unlike-type squarks, we also have

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{q}_i\bar{\tilde{q}}_j) = \frac{2\pi\alpha_s^2}{9s^2} \frac{m_{\tilde{g}}^2s}{(t-m_{\tilde{g}}^2)^2}.$$
 (44.56)

There also exist cross sections for quark-quark annihilation to squark pairs. For same flavor quark-quark annihilation to same flavor/same type final state squarks,

$$\frac{d\sigma}{dt}(qq \to \tilde{q}_i \tilde{q}_i) =$$

$$= \frac{\pi \alpha_s^2}{9s^2} m_{\tilde{g}}^2 s \left\{ \frac{1}{(t - m_{\tilde{g}}^2)^2} + \frac{1}{(u - m_{\tilde{g}}^2)^2} - \frac{2/3}{(t - m_{\tilde{g}}^2)(u - m_{\tilde{g}}^2)} \right\}, (44.57)$$

while if the final type squarks are different $(i \neq j)$, we have

$$\frac{d\sigma}{dt}(qq \rightarrow \tilde{q}_i\tilde{q}_j) =$$

$$\frac{2\pi\alpha_s^2}{9s^2} \left\{ \frac{\left[-st - (t - m_{\tilde{q}_i}^2)(t - m_{\tilde{q}_j}^2) \right]}{(t - m_{\tilde{g}}^2)} + \frac{\left[-su - (u - m_{\tilde{q}_i}^2)(u - m_{\tilde{q}_j}^2) \right]}{(u - m_{\tilde{g}}^2)} \right\}.$$

$$(44.58)$$

If initial/final state flavors are different, but final state squark types are the same, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i \tilde{q}_i') = \frac{2\pi\alpha_s^2}{9s^2} \frac{m_{\tilde{\varrho}}^2 s}{(t - m_{\tilde{\varrho}}^2)^2}.$$
 (44.59)

If initial quark flavors are different and final squark types are different, then

$$\frac{d\sigma}{dt}(qq' \to \tilde{q}_i \tilde{q}'_j) = \frac{2\pi\alpha_s^2}{9s^2} \frac{-st - (t - m_{\tilde{q}_i}^2)(t - m_{\tilde{q}_j}^2)}{(t - m_{\tilde{\varrho}}^2)^2}.$$
 (44.60)

44.8.2. Gluino and squark associated production:

In the MSSM, the charged spin- $\frac{1}{2}$ winos and higgsinos mix to make chargino states χ_1^\pm and $\chi_2^\pm,$ with $m_{\chi_1^\pm} < m_{\chi_2^\pm}.$ The spin- $\frac{1}{2}$ neutral bino, wino and higgsino fields mix to give four neutralino mass eigenstates $\chi_{1,2,3,4}^0$ ordered according to mass. We sometimes denote the charginos and neutralinos collectively as -inos for notational simplicity

For gluino and squark production in association with charginos and neutralinos [12], the quark-squark-neutralino couplings* are defined by the interaction Lagrangian terms $\mathcal{L}_{\tilde{f}f\tilde{\chi}_{0}^{0}}=$

 $\begin{bmatrix} iA_{\tilde{\chi}_i^0}^f \tilde{f}_L^\dagger \bar{\chi}_i^0 P_L f + iB_{\tilde{\chi}_i^0}^f \tilde{f}_R^\dagger \bar{\chi}_i^0 P_R f + \text{h.c.} \end{bmatrix}, \text{ where } A_{\tilde{\chi}_i^0}^f \text{ and } B_{\tilde{\chi}_i^0}^f \text{ are coupling constants involving gauge couplings, neutralino mixing elements and in the case of third generation fermions, Yukawa couplings. Their form depends on the conventions used for setting up the MSSM Lagrangian, and can be found in various reviews [13] and textbooks [14,15]. <math>P_L$ and P_R are the usual left- and right-spinor projection operators and f denotes any of the SM fermions u, d, e, ν_e, \cdots . The fermion-sfermion- chargino couplings have the form $\mathcal{L} = \left[iA_{\tilde{\chi}_i^-}^d \tilde{u}_L^\dagger \overline{\tilde{\chi}_i^-} P_L d + iA_{\tilde{\chi}_i^-}^u d_L^\dagger \overline{\tilde{\chi}_i^c} P_L u + \text{h.c.}\right]$ for u and d quarks, where the $A_{\tilde{\chi}_i^-}^d$ and $A_{\tilde{\chi}_i^-}^u$ couplings are again convention-dependent, and can be found in textbooks. The superscript c denotes "charge conjugate spinor", defined by $\psi^c \equiv C\bar{\psi}^T$.

The subprocess cross sections for chargino-squark associated production occur via squark exchange and are given by

$$\frac{d\sigma}{dt}(\bar{u}g \rightarrow \tilde{\chi}_{i}^{-}\bar{d}_{L}) = \frac{\alpha_{s}}{24s^{2}}|A_{\tilde{\chi}_{i}^{-}}^{u}|^{2}\psi(m_{\tilde{d}_{L}}, m_{\tilde{\chi}_{i}^{-}}, t), \quad (44.61)$$

$$\frac{d\sigma}{dt}(dg \rightarrow \tilde{\chi}_i^- \tilde{u}_L) = \frac{\alpha_s}{24s^2} |A_{\tilde{\chi}_i^-}^d|^2 \psi(m_{\tilde{u}_L}, m_{\tilde{\chi}_i^-}, t), \tag{44.62} \label{eq:4.62}$$

while neutralino-squark production is given by

$$\frac{d\sigma}{dt}(qg \to \tilde{\chi}^0_i \tilde{q}) = \frac{\alpha_s}{24s^2} \left(|A^q_{\tilde{\chi}^0_i}|^2 + |B^q_{\tilde{\chi}^0_i}|^2 \right) \psi(m_{\tilde{q}}, m_{\tilde{\chi}^0_i}, t), \quad (44.63)$$

where

$$\psi(m_1, m_2, t) = \frac{s + t - m_1^2}{2s} - \frac{m_1^2(m_2^2 - t)}{(m_1^2 - t)^2} + \frac{t(m_2^2 - m_1^2) + m_2^2(s - m_2^2 + m_1^2)}{s(m_1^2 - t)}.$$
 (44.64)

Here, the variable t is given by the square of "squark-minus-quark" four-momentum. The neutralino-gluino associated production cross section also occurs via squark exchange and is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\chi}_{i}^{0}\tilde{g}) = \frac{\alpha_{s}}{18s^{2}} \left(|A_{\tilde{\chi}_{i}^{0}}^{q}|^{2} + |B_{\tilde{\chi}_{i}^{0}}^{q}|^{2} \right) \left[\frac{(m_{\tilde{\chi}_{i}^{0}}^{2} - t)(m_{\tilde{g}}^{2} - t)}{(m_{\tilde{q}}^{2} - t)^{2}} + \frac{(m_{\tilde{\chi}_{i}^{0}}^{2} - u)(m_{\tilde{g}}^{2} - u)}{(m_{\tilde{q}}^{2} - u)^{2}} - \frac{2\eta_{i}\eta_{\tilde{g}}m_{\tilde{g}}m_{\tilde{\chi}_{i}^{0}}s}{(m_{\tilde{q}}^{2} - t)(m_{\tilde{q}}^{2} - u)} \right], (44.65)$$

where η_i is the sign of the neutralino mass eigenvalue and $\eta_{\tilde{g}}$ is the sign of the gluino mass eigenvalue. We also have chargino-gluino associated production:

$$\frac{d\sigma}{dt}(\bar{u}d \to \tilde{\chi}_i^- \tilde{g}) = \frac{\alpha_s}{18s^2} \left[|A_{\tilde{\chi}_i}^u|^2 \frac{(m_{\tilde{\chi}_i^-}^2 - t)(m_{\tilde{g}}^2 - t)}{(m_{\tilde{d}_I}^2 - t)^2} \right]$$

$$+|A_{\tilde{\chi}_{i}^{-}}^{d}|^{2}\frac{(m_{\tilde{\chi}_{i}^{-}}^{2}-u)(m_{\tilde{g}}^{2}-u)}{(m_{\tilde{u}_{L}}^{2}-u)^{2}}+\frac{2\eta_{\tilde{g}}Re(A_{\tilde{\chi}_{i}^{-}}^{u}A_{\tilde{\chi}_{i}^{-}}^{d})m_{\tilde{g}}m_{\tilde{\chi}_{i}}s}{(m_{\tilde{d}_{I}}^{2}-t)(m_{\tilde{u}_{L}}^{2}-u)}\right],~(44.66)$$

where $\hat{t} = (\tilde{g} - d)^2$ and in the third term one must take the real part of the in general complex coupling constant product.

44.8.3. Slepton and sneutrino production:

The subprocess cross section for $\tilde{\ell}_L \tilde{\bar{\nu}}_{\ell_L}$ production $(\ell = e \text{ or } \mu)$ occurs via s-channel W exchange and is given by

$$\frac{d\sigma}{dt}(d\bar{u} \to \tilde{\ell}_L \bar{\tilde{\nu}}_{\ell_L}) = \frac{g^4 |D_W(s)|^2}{192\pi s^2} \left(tu - m_{\tilde{\ell}_L}^2 m_{\tilde{\nu}_{\ell_L}}^2 \right), \tag{44.67}$$

where $D_W(s)=1/(s-M_W^2+iM_W\Gamma_W)$ is the W-boson propagator denominator. The production of $\tilde{\tau}_1\bar{\tilde{\nu}}_{\tau}$ is given as above, but replacing $m_{\tilde{\ell}_L} \to m_{\tilde{\tau}_1}, \ m_{\tilde{\nu}_{\ell}_L} \to m_{\tilde{\nu}_{\tau}}$ and multiplying by an overall factor of $\cos^2\theta_{\tau}$ (where θ_{τ} is the tau-slepton mixing angle). Similar substitutions hold for $\tilde{\tau}_2\bar{\tilde{\nu}}_{\tau}$ production, except the overall factor is $\sin^2\theta_{\tau}$.

Table 44.1: The constants α_f and β_f that appear in in the SM neutral current Lagrangian. Here $t \equiv \tan \theta_W$ and $c \equiv \cot \theta_W$.

| \overline{f} | q_f | α_f | eta_f |
|----------------|----------------|---------------------------------|---------------------|
| ℓ | -1 | $\frac{1}{4}(3t-c)$ | $\frac{1}{4}(t+c)$ |
| ν_ℓ | 0 | $\frac{1}{4}(t+c)$ | $-\frac{1}{4}(t+c)$ |
| u | $\frac{2}{3}$ | $-\frac{5}{12}t + \frac{1}{4}c$ | $-\frac{1}{4}(t+c)$ |
| d | $-\frac{1}{3}$ | $\frac{1}{12}t - \frac{1}{4}c$ | $\frac{1}{4}(t+c)$ |

^{*} The couplings $A_{\tilde{\chi}_{i}^{0}}^{f}$ and $B_{\tilde{\chi}_{i}^{0}}^{f}$ are given explicitly in Ref. 15 in Eq. (8.87). Also, the couplings $A_{\tilde{\chi}_{i}^{-}}^{d}$ and $A_{\tilde{\chi}_{i}^{-}}^{u}$ are given in Eq. (8.93). The couplings X_{i}^{j} and Y_{i}^{j} are given by Eq. (8.103), while the x_{i} and y_{i} couplings are given in Eq. (8.100). Finally, the couplings W_{ij} are given in Eq. (8.101).

The subprocess cross section for $\tilde{\ell}_L\bar{\tilde{\ell}}_L$ production occurs via schannel γ and Z exchange, and depends on the neutral current interaction, with fermion couplings to γ and Z^0 given by $\mathcal{L}_{\text{neutral}} = -eq_f\bar{f}\gamma^\mu fA_\mu + e\bar{f}\gamma^\mu (\alpha_f + \beta_f\gamma_5)fZ_\mu$ (with values of q_f , α_f , and β_f given in Table 44.1.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{\ell}_L \bar{\tilde{\ell}}_L) = \frac{e^4}{24\pi s^2} \left(tu - m_{\tilde{\ell}_L}^4\right) \times \left\{ \frac{q_\ell^2 q_q^2}{s^2} + (\alpha_\ell - \beta_\ell)^2 (\alpha_q^2 + \beta_q^2) |D_Z(s)|^2 + \frac{2q_\ell q_q \alpha_q (\alpha_\ell - \beta_\ell) (s - M_Z^2)}{s} |D_Z(s)|^2 \right\}, \tag{44.68}$$

where $D_Z(s)=1/(s-M_Z^2+iM_Z\Gamma_Z)$. The cross section for sneutrino production is given by the same formula, but with $\alpha_\ell,\,\beta_\ell,\,q_\ell$ and $m_{\tilde\ell_L}$ replaced by $\alpha_\nu,\,\beta_\nu,\,0$ and $m_{\tilde\nu_L}$, respectively. The cross section for $\tilde\tau_1\bar{\tilde\tau}_1$ production is obtained by replacing $m_{\tilde\ell_L}\to m_{\tilde\tau_1}$ and $\beta_\ell\to\beta_\ell\cos2\theta_\tau$. The cross section for $\tilde\ell_R\bar{\tilde\ell}_R$ production is given by substituting $\alpha_\ell-\beta_\ell\to\alpha_\ell+\beta_\ell$ and $m_{\tilde\ell_L}\to m_{\tilde\ell_R}$ in the equation above. The cross section for $\tilde\tau_2\bar{\tilde\tau}_2$ production is obtained from the formula for $\tilde\ell_R\bar{\tilde\ell}_R$ production by replacing $m_{\tilde\ell_R}\to m_{\tilde\tau_2}$ and $\beta_\ell\to\beta_\ell\cos2\theta_\tau$.

Finally, the cross section for $\tilde{\tau}_1\tilde{\tilde{\tau}}_2$ production occurs only via Z exchange, and is given by

$$\frac{d\sigma}{dt}(q\bar{q}\to\tilde{\tau}_1\bar{\tilde{\tau}}_2) = \frac{d\sigma}{dt}(q\bar{q}\to\bar{\tilde{\tau}}_1\tilde{\tau}_2) =$$

$$\frac{e^4}{24\pi s^2} (\alpha_q^2 + \beta_q^2) \beta_\ell^2 \sin^2 2\theta_\tau |D_Z(s)|^2 (ut - m_{\tilde{\tau}_1}^2 m_{\tilde{\tau}_2}^2). \tag{44.69}$$

44.8.4. Chargino and neutralino pair production:

44.8.4.1. $\tilde{\chi}_i^- \tilde{\chi}_i^0$ production:

The subprocess cross section for $d\bar{u}\to \tilde{\chi}_i^-\tilde{\chi}_j^0$ depends on Lagrangian couplings $\mathcal{L}_{W\bar{u}d}=-\frac{g}{\sqrt{2}}\bar{u}\gamma_\mu P_L dW^{+\mu}+\text{h.c.},\,\mathcal{L}_{W\tilde{\chi}_i^-\tilde{\chi}_j^0}=-g(-i)^{\theta j}\overline{\chi}_i^-[X_i^j+Y_i^j\gamma_5]\gamma_\mu\tilde{\chi}_j^0W^{-\mu}+\text{h.c.},\,\mathcal{L}_{q\bar{q}\tilde{\chi}_i^-}=iA_{\tilde{\chi}_i}^d\,\bar{u}_L^\dagger\tilde{\chi}_i^-P_L d+iA_{\tilde{\chi}_i^-}^u\,\bar{d}_L^\dagger\overline{\chi}_i^cP_L u+\text{h.c.}$ and $\mathcal{L}_{q\bar{q}\tilde{\chi}_j^0}=iA_{\tilde{\chi}_j^0}^q\,\bar{d}_L^\dagger\overline{\chi}_j^0\,p_L q+\text{h.c.}$. Contributing diagrams include W exchange and also \tilde{d}_L and \tilde{u}_L squark exchange. The X_i^j and Y_i^j couplings are new, and again convention-dependent: the cross section formulae works if the interaction Lagrangian is written in the above form, so that the couplings can be suitably extracted. The term $\theta_j=0$ (1) if $m_{\tilde{\chi}_j^0}>0$ (<0); it comes about because the neutralino field must be re-defined by a $-i\gamma_5$ transformation if its mass eigenvalue is negative [15]. The subprocess cross section is given in terms of dot products of four momenta, where particle labels are used to denote their four-momenta; note that all mass terms in the cross section formulae are positive definite, so that the signs of mass eigenstates have been absorbed into the Lagrangian couplings, as for instance in Ref. [15]. We then have

$$\begin{split} \frac{d\sigma}{dt}(d\overline{u} \rightarrow \tilde{\chi}_i^- \tilde{\chi}_j^0) &= \frac{1}{192\pi s^2} \\ \\ \left[T_W + T_{\tilde{d}_L} + T_{\tilde{u}_L} + T_{W\tilde{d}_L} + T_{W\tilde{u}_L} + T_{\tilde{d}_L\tilde{u}_L} \right] \end{split} \tag{44.70}$$

where

$$T_{W} = 8g^{4}|D_{W}(s)|^{2} \left\{ [X_{i}^{j2} + Y_{i}^{j2}](\tilde{\chi}_{j}^{0} \cdot d\tilde{\chi}_{i}^{-} \cdot \overline{u} + \tilde{\chi}_{j}^{0} \cdot \overline{u}\tilde{\chi}_{i}^{-} \cdot d) + 2(X_{i}^{j}Y_{i}^{j})(\tilde{\chi}_{j}^{0} \cdot d\tilde{\chi}_{i}^{-} \cdot \overline{u} - \tilde{\chi}_{j}^{0} \cdot \overline{u}\tilde{\chi}_{i}^{-} \cdot d) + [X_{i}^{j2} - Y_{i}^{j2}]m_{\tilde{\chi}_{i}^{-}}m_{\tilde{\chi}_{j}^{0}}d \cdot \overline{u} \right\},$$

$$(44.71)$$

$$T_{\tilde{d}_L} = \frac{4|A^u_{\tilde{\chi}_i^-}|^2|A^d_{\tilde{\chi}_j^0}|^2}{[(\tilde{\chi}_i^- - \overline{u})^2 - m^2_{\tilde{d}_I}]^2} \; d \cdot \tilde{\chi}_j^0 \tilde{\chi}_i^- \cdot \overline{u}, \tag{44.72}$$

$$T_{\tilde{u}_L} = \frac{4|A_{\tilde{\chi}_i}^d|^2|A_{\tilde{\chi}_j^0}^u|^2}{[(\tilde{\chi}_j^0 - \overline{u})^2 - m_{\tilde{u}_L}^2]^2} \, \overline{u} \cdot \tilde{\chi}_j^0 \tilde{\chi}_i^- \cdot d \tag{44.73}$$

$$\begin{split} T_{W\tilde{d}_{L}} &= \frac{-\sqrt{2}g^{2}Re[A_{\tilde{\chi}_{j}^{0}}^{d*}A_{\tilde{\chi}_{i}^{-}}^{u}(-i)^{\theta_{j}}](s-M_{W}^{2})|D_{W}(s)|^{2}}{(\tilde{\chi}_{i}^{-}-\overline{u})^{2}-m_{\tilde{d}_{L}}^{2}} \\ &\times \left\{8(X_{i}^{j}+Y_{i}^{j})\tilde{\chi}_{j}^{0}\cdot d\overline{u}\cdot\tilde{\chi}_{i}^{-}+4(X_{i}^{j}-Y_{i}^{j})m_{\tilde{\chi}_{i}^{-}}m_{\tilde{\chi}_{j}^{0}}d\cdot\overline{u}\right\}(44.74) \end{split}$$

$$\begin{split} T_{W\tilde{u}_{L}} &= \frac{\sqrt{2}g^{2}Re[A^{d*}_{\tilde{\chi}_{i}^{-}}A^{u}_{\tilde{\chi}_{j}^{0}}(-i)^{\theta_{j}}](s-M_{W}^{2})|D_{W}(s)|^{2}}{(\tilde{\chi}_{j}^{0}-\overline{u})^{2}-m_{\tilde{u}_{L}}^{2}} \\ &\times \left\{8(X^{j}_{i}-Y^{j}_{i})\tilde{\chi}_{j}^{0}\cdot\overline{u}d\cdot\tilde{\chi}_{i}^{-}+4(X^{j}_{i}+Y^{j}_{i})m_{\tilde{\chi}_{i}^{-}}m_{\tilde{\chi}_{j}^{0}}d\cdot\overline{u}\right\}(44.75) \end{split}$$

and

$$T_{\tilde{d}_L\tilde{u}_L} = -\frac{4Re[A_{\tilde{\chi}_j}^d A_{\tilde{\chi}_i}^{u*} A_{\tilde{\chi}_i}^{d*} A_{\tilde{\chi}_i}^u] m_{\tilde{\chi}_i} m_{\tilde{\chi}_j}^0 d \cdot \overline{u}}{[(\tilde{\chi}_i^- - \overline{u})^2 - m_{\tilde{d}_L}^2][(\tilde{\chi}_j^0 - \overline{u})^2 - m_{\tilde{u}_L}^2]}. \tag{44.76}$$

44.8.4.2. Chargino pair production:

The subprocess cross section for $d\bar{d} \to \tilde{\chi}_i^- \tilde{\chi}_i^+ \ (i=1,2)$ depends on Lagrangian couplings $\mathcal{L} = e \overline{\tilde{\chi}_i^-} \gamma_\mu \tilde{\chi}_i^- A^\mu - e \cot \theta_W \overline{\tilde{\chi}_i^-} \gamma_\mu (x_i - y_i \gamma_5) \tilde{\chi}_i^- Z^\mu$ and also $\mathcal{L} \ni i A_{\tilde{\chi}_i}^d \tilde{u}_L^\dagger \overline{\tilde{\chi}_i^-} P_L d + i A_{\tilde{\chi}_i}^u \tilde{d}_L^\dagger \overline{\tilde{\chi}_i^-} P_L u + \text{h.c.}$. Contributing diagrams include s-channel γ , Z^0 exchange and t-channel \tilde{u}_L exchange [16,17]. The couplings x_i and y_i are again new and as usual convention-dependent.

The subprocess cross section is given by

$$\frac{d\sigma}{dt}(d\overline{d} \to \tilde{\chi}_i^- \tilde{\chi}_i^+) = \frac{1}{192\pi s^2} \left[T_{\gamma} + T_{Z} + T_{\tilde{u}_L} + T_{\gamma Z} + T_{\gamma \tilde{u}_L} + T_{Z\tilde{u}_L} \right]$$
(44.77)

where

$$T_{\gamma} = \frac{32e^4q_d^2}{s^2} \left[d \cdot \tilde{\chi}_i^+ \overline{d} \cdot \tilde{\chi}_i^- + d \cdot \tilde{\chi}_i^- \overline{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i}^2 d \cdot \overline{d} \right]$$

$$T_Z = 32e^4 \cot^2 \theta_W |D_Z(s)|^2$$

$$(44.78)$$

$$\left\{ (\alpha_d^2 + \beta_d^2)(x_i^2 + y_i^2) \left[d \cdot \tilde{\chi}_i^+ \overline{d} \cdot \tilde{\chi}_i^- + d \cdot \tilde{\chi}_i^- \overline{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i}^2 d \cdot \overline{d} \right] \right\}$$

$$\mp 4\alpha_{d}\beta_{d}x_{i}y_{i}\left[d\cdot\tilde{\chi}_{i}^{+}\overline{d}\cdot\tilde{\chi}_{i}^{-}-d\cdot\tilde{\chi}_{i}^{-}\overline{d}\cdot\tilde{\chi}_{i}^{+}\right]-2y_{i}^{2}(\alpha_{d}^{2}+\beta_{d}^{2})m_{\tilde{\chi}_{i}}^{2}-d\cdot\overline{d}\bigg\},$$

$$(44.79)$$

$$T_{\tilde{u}_L} = \frac{4|A_{\tilde{\chi}_i}^d|^4}{[(d - \tilde{\chi}_i^-)^2 - m_{\tilde{u}_L}^2]^2} d \cdot \tilde{\chi}_i^- \overline{d} \cdot \tilde{\chi}_i^+$$
(44.80)

$$T_{\gamma Z} = \frac{64e^4 \cot \theta_W q_d(s - M_Z^2)|D_Z(s)|^2}{\epsilon} \times$$

$$\left\{ \alpha_{d} x_{i} \left(d \cdot \tilde{\chi}_{i}^{+} \overline{d} \cdot \tilde{\chi}_{i}^{-} + d \cdot \tilde{\chi}_{i}^{-} \overline{d} \cdot \tilde{\chi}_{i}^{+} + m_{\tilde{\chi}_{i}^{-}}^{2} d \cdot \overline{d} \right) \right. \\
\left. \pm \beta_{d} y_{i} \left(d \cdot \tilde{\chi}_{i}^{-} \overline{d} \cdot \tilde{\chi}_{i}^{+} - d \cdot \tilde{\chi}_{i}^{+} \overline{d} \cdot \tilde{\chi}_{i}^{-} \right) \right\} \tag{44.81}$$

$$T_{\gamma \tilde{u}_{L}} = \mp \frac{8e^{2}q_{d}}{s} \frac{|A_{\tilde{\chi}_{i}}^{d}|^{2}}{[(d - \tilde{\chi}_{i}^{-})^{2} - m_{\tilde{u}_{L}}^{2}]} \left\{ 2\overline{d} \cdot \tilde{\chi}_{i}^{+} d \cdot \tilde{\chi}_{i}^{-} + m_{\tilde{\chi}_{i}}^{2} d \cdot \overline{d} \right\}$$

$$(44.82)$$

and

$$T_{Z\bar{u}_L} = \mp 8e^2 \cot \theta_W |D_Z(s)|^2 \frac{|A_{\tilde{\chi}_i}^d|^2 (s - M_Z^2)}{[(d - \tilde{\chi}_i^-)^2 - m_{\tilde{u}_L}^2]} (\alpha_d - \beta_d) \times \left\{ 2(x_i \mp y_i)d \cdot \tilde{\chi}_i^- \overline{d} \cdot \tilde{\chi}_i^+ + m_{\tilde{\chi}_i^-}^2 (x_i \pm y_i)d \cdot \overline{d} \right\}$$
(44.83)

using the upper of the sign choices.

The cross section for $u\overline{u} \to \tilde{\chi}_i^+ \tilde{\chi}_i^-$ can be obtained from the above by replacing $\alpha_d \to \alpha_u$, $\beta_d \to \beta_u$, $q_d \to q_u$, $\tilde{u}_L \to \tilde{d}_L$, $A_{\tilde{\chi}_i^-}^d \to A_{\tilde{\chi}_i^-}^u$, $d \to \overline{u}$, $\overline{d} \to u$ and adopting the lower of the sign choices everywhere.

The cross section for $q\bar{q} \to \tilde{\chi}_1^- \tilde{\chi}_2^+$, $\tilde{\chi}_1^+ \tilde{\chi}_2^-$ can occur via Z and \tilde{q}_L exchange. It is usually much smaller than $\tilde{\chi}_{1,2}^- \tilde{\chi}_{1,2}^+$ production, so the cross section will not be presented here. It can be found in Appendix A of Ref. 15.

44.8.4.3. Neutralino pair production:

Neutralino pair production via $q\bar{q}$ fusion takes place via s-channel Z exchange plus t- and u-channel left- and right- squark exchange (5 diagrams) [17,18]. The Lagrangian couplings (see previous footnote*) needed include terms given above plus terms of the form $\mathcal{L} = W_{ij}\bar{\chi}^{\bar{0}}_{i}\gamma_{\mu}(\gamma_{5})^{\theta_{i}+\theta_{j}+1}\tilde{\chi}^{0}_{j}Z^{\mu}$. The couplings W_{ij} depend only on the higgsino components of the neutralinos i and j. The subprocess cross section is given by:

$$\frac{d\sigma}{dt}(q\bar{q} \to \tilde{\chi}_{i}^{0}\tilde{\chi}_{j}^{0}) = \frac{1}{192\pi s^{2}} \left[T_{Z} + T_{\tilde{q}_{L}} + T_{\tilde{q}_{R}} + T_{Z\tilde{q}_{L}} + T_{Z\tilde{q}_{R}} \right] (44.84)$$

where

$$T_{Z} = 128e^{2}|W_{ij}|^{2}(\alpha_{q}^{2} + \beta_{q}^{2})|D_{Z}(s)|^{2}$$

$$\left[q \cdot \tilde{\chi}_{i}^{0} \bar{q} \cdot \tilde{\chi}_{j}^{0} + q \cdot \tilde{\chi}_{j}^{0} \bar{q} \cdot \tilde{\chi}_{i}^{0} - \eta_{i}\eta_{j}m_{\tilde{\chi}_{i}^{0}}m_{\tilde{\chi}_{j}^{0}}q \cdot \bar{q}\right], \qquad (44.85)$$

$$T_{\tilde{q}_{L}} = 4|A_{\tilde{\chi}_{i}^{0}}^{q}|^{2}|A_{\tilde{\chi}_{j}^{0}}^{q}|^{2} \left\{ \frac{q \cdot \tilde{\chi}_{i}^{0} \bar{q} \cdot \tilde{\chi}_{j}^{0}}{[(\tilde{\chi}_{i}^{0} - q)^{2} - m_{\tilde{q}_{L}}^{2}]^{2}} + \frac{q \cdot \tilde{\chi}_{j}^{0} \bar{q} \cdot \tilde{\chi}_{i}^{0}}{[(\tilde{\chi}_{j}^{0} - q)^{2} - m_{\tilde{q}_{L}}^{2}]^{2}} - \eta_{i} \eta_{j} \frac{m_{\tilde{\chi}_{i}^{0}} m_{\tilde{\chi}_{j}^{0}} q \cdot \bar{q}}{[(\tilde{\chi}_{i}^{0} - q)^{2} - m_{\tilde{q}_{L}}^{2}][(\tilde{\chi}_{j}^{0} - q)^{2} - m_{\tilde{q}_{L}}^{2}]} \right\}$$

$$(44.86)$$

$$\begin{split} T_{\bar{q}_R} &= 4|B_{\tilde{\chi}_i^0}^q|^2|B_{\tilde{\chi}_j^0}^q|^2 \left\{ \frac{q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2]^2} + \frac{q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0}{[(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_R}^2]^2} \right. \\ &- \eta_i \eta_j \frac{m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q}}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2][(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_R}^2]} \right\} \\ &- \eta_i \eta_j \frac{m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q}}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2][(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_R}^2]} \right\} \\ &- \left\{ \frac{Re(W_{ij} A_{\tilde{\chi}_i^0}^{q*} A_{\tilde{\chi}_j^0}^q)}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_L}^2]} \left[2q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right. \\ &+ \eta_i \eta_j \frac{Re(W_{ij} A_{\tilde{\chi}_i^0}^q A_{\tilde{\chi}_j^0}^q)}{[(\tilde{\chi}_j^0 - q)^2 - m_{\tilde{q}_L}^2]} \left[2q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right\} \\ &- \frac{Re(W_{ij} B_{\tilde{\chi}_i^0}^{q*} B_{\tilde{\chi}_j^0}^q)}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2]} \left[2q \cdot \tilde{\chi}_i^0 \bar{q} \cdot \tilde{\chi}_j^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \\ &- \frac{Re(W_{ij} B_{\tilde{\chi}_i^0}^q B_{\tilde{\chi}_j^0}^q)}{[(\tilde{\chi}_i^0 - q)^2 - m_{\tilde{q}_R}^2]} \left[2q \cdot \tilde{\chi}_j^0 \bar{q} \cdot \tilde{\chi}_i^0 - \eta_i \eta_j m_{\tilde{\chi}_i^0} m_{\tilde{\chi}_j^0} q \cdot \bar{q} \right] \right\}. \end{aligned} \tag{44.89}$$

As before, $\eta_i=\pm 1$ corresponding to whether the neutralino mass eigenvalue is positive or negative. When i=j in the above formula, one must remember to integrate over just 2π steradians of solid angle to avoid double counting in the total cross section.

44.9. Universal extra dimensions

In the Universal Extra Dimension (UED) model of Ref. [19] (see Ref. [20] for a review of models with extra spacetime dimensions), the Standard Model is embedded in a five dimensional theory, where the fifth dimension is compactified on an S_1/Z_2 orbifold. Each SM chirality state is then the zero mode of an infinite tower of Kaluza-Klein excitations labelled by $n=0-\infty$. A KK parity is usually assumed to hold, where each state is assigned KK-parity $P=(-1)^n$. If the compactification scale is around a TeV, then the n=1 (or even higher) KK modes may be accessible to collider searches.

Of interest for hadron colliders are the production of massive $n \geq 1$ quark or gluon pairs. These production cross sections have been calculated in Ref. [21,22]. We list here results for the n=1 case only with $M_1=1/R$ (R is the compactification radius) and s,t and u are the usual Mandelstam variables; more general formulae can be found in Ref. [22]. The superscript * stands for any KK excited state, while • stands for left chirality states and o stands for right chirality states.

$$\frac{d\sigma}{dt} = \frac{1}{16\pi s^2} T \tag{44.90}$$

where

$$T(q\bar{q} \to g^*g^*) = \frac{2g_s^4}{27} \left[M_1^2 \left(-\frac{4s^3}{t'^2u'^2} + \frac{57s}{t'u'} - \frac{108}{s} \right) + \frac{20s^2}{t'u'} - 93 + \frac{108t'u'}{s^2} \right]$$
(44.91)

and

$$T(gg \to g^*g^*) = \frac{9g_s^4}{27} \left[3M_1^4 \frac{s^2 + t'^2 + u'^2}{t'^2u'^2} - 3M_1^2 \frac{s^2 + t'^2 + u'^2}{st'u'} + 1 + \frac{(s^2 + t'^2 + u'^2)^3}{4s^2t'^2u'^2} - \frac{t'u'}{s^2} \right]$$
(44.92)

where $t' = t - M_1^2$ and $u' = u - M_1^2$.

Alsc

$$\begin{split} T(q\bar{q} \to q_1^{*'}\bar{q}_1^{*'}) &= \frac{4g_s^4}{9} \left[\frac{2M_1^2}{s} + \frac{t'^2 + u'^2}{s^2} \right], \\ T(q\bar{q} \to q_1^*\bar{q}_1^*) &= \frac{g_2^4}{9} \left[2M_1^2 \left(\frac{4}{s} + \frac{s}{t'^2} - \frac{1}{t'} \right) \right. \\ &\quad + \frac{23}{6} + \frac{2s^2}{t'^2} + \frac{8s}{3t'} + \frac{6t'}{s} + \frac{8t'^2}{s^2} \right], \\ T(qq \to q_1^*q_1^*) &= \frac{g_s^4}{27} \left[M_1^2 \left(6\frac{t'}{u'^2} + 6\frac{u'}{t'^2} - \frac{s}{t'u'} \right) \right. \\ &\quad + 2 \left(3\frac{t'^2}{u'^2} + 3\frac{u'^2}{t'^2} + 4\frac{s^2}{t'u'} - 5 \right) \right], \\ T(gg \to q_1^*\bar{q}_1^*) &= g_s^4 \left[M_1^4 \frac{-4}{t'u'} \left(\frac{s^2}{6t'u'} - \frac{3}{8} \right) \right. \\ &\quad + M_1^2 \frac{4}{s} \left(\frac{s^2}{6t'u'} - \frac{3}{8} \right) + \frac{s^2}{6t'u'} - \frac{17}{24} + \frac{3t'u'}{4s^2} \right], \\ T(gq \to g^*q_1^*) &= \frac{-g_s^4}{3} \left[\frac{5s^2}{12t'^2} + \frac{s^3}{t'^2u'} + \frac{11su'}{6t'^2} + \frac{5u'^2}{12t'^2} + \frac{u'^3}{st'^2} \right], \\ T(q\bar{q}' \to q_1^*\bar{q}_1^{*'}) &= \frac{g_s^4}{18} \left[4M_1^4 \frac{s}{t'^2} + 5 + 4\frac{s^2}{t'^2} + 8\frac{s}{t'} \right], \\ T(qq' \to q_1^*q_1^{*'}) &= \frac{2g_s^4}{9} \left[-M_1^2 \frac{s}{t'^2} + \frac{1}{4} + \frac{s^2}{t'^2} \right], \end{split}$$

$$\begin{split} T(qq \to q_1^{\bullet} q_1^{\circ}) &= \frac{g_s^4}{9} \left[M_1^2 \left(\frac{2s^3}{t'^2 u'^2} - \frac{4s}{t' u'} \right) + 2 \frac{s^4}{t'^2 u'^2} - 8 \frac{s^2}{t' u'} + 5 \right], \\ T(q\bar{q}' \to q_1^{\bullet} \bar{q}_1'^{\circ}) &= \frac{g_s^4}{9} \left[2M_1^2 \left(\frac{1}{t'} + \frac{u'}{t'^2} \right) + \frac{5}{2} + \frac{4u'}{t'} + \frac{2u'^2}{t'^2} \right], \end{split}$$

and

$$T(qq' \to q_1^{\bullet} q_1'^{\circ}) = \frac{g_s^4}{9} \left[-2M_1^2 \left(\frac{1}{t'} + \frac{u'}{t'^2} \right) + \frac{1}{2} + \frac{2u'^2}{t'^2} \right].$$

44.10. Large extra dimensions

In the ADD theory [23] with large extra dimensions (LED), the SM particles are confined to a 3-brane, while gravity propagates in the bulk. It is assumed that the n extra dimensions are compactified on an n-dimensional torus of volume $(2\pi r)^n$, so that the fundamental 4+n dimensional Planck scale M_* is related to the usual 4-dimensional Planck scale M_{Pl} by $M_{Pl}^2 = M_*^{n+2}(2\pi r)^n$. If $M_* \sim 1$ TeV, then the $M_W - M_{Pl}$ hierarchy problem is just due to gravity propagating in the large extra dimensions.

In these theories, the KK-excited graviton states $G^n_{\mu\nu}$ for $n=1-\infty$ can be produced at collider experiments. The graviton couplings to matter are suppressed by $1/M_{Pl}$, so that graviton emission cross sections $d\sigma/dt\sim 1/M_{Pl}^2$. However, the mass splittings between the excited graviton states can be tiny, so the graviton eigenstates are usually approximated by a continuum distribution. A summation (integration) over all allowed graviton emissions ends up cancelling the $1/M_{Pl}^2$ factor, so that observable cross section rates can be attained. Some of the fundamental production formulae for a KK graviton (denoted G) of mass m at hadron colliders include the subprocesses

$$\frac{d\sigma_m}{dt}(f\bar{f}\to\gamma G) = \frac{\alpha Q_f^2}{16N_f} \frac{1}{sM_{DI}^2} F_1(\frac{t}{s}, \frac{m^2}{s}), \tag{44.93}$$

where Q_f is the charge of fermion f and N_f is the number of QCD colors of f. Also,

$$\frac{d\sigma_m}{dt}(q\bar{q} \rightarrow gG) = \frac{\alpha_s}{36} \frac{1}{sM_{Pl}^2} F_1(\frac{t}{s}, \frac{m^2}{s}), \tag{44.94}$$

$$\frac{d\sigma_m}{dt}(qg \to qG) = \frac{\alpha_s}{96} \frac{1}{sM_{Pl}^2} F_2(\frac{t}{s}, \frac{m^2}{s}), \tag{44.95}$$

$$\frac{d\sigma_m}{dt}(gg \to gG) = \frac{3\alpha_s}{16} \frac{1}{sM_{Pl}^2} F_3(\frac{t}{s}, \frac{m^2}{s}), \tag{44.96}$$

where

$$\begin{split} F_1(x,y) = & \frac{1}{x(y-1-x)} \left[-4x(1+x)(1+2x+2x^2) + \right. \\ & \left. y(1+6x+18x^2+16x^3) - 6y^2x(1+2x) + y^3(1+4x) \right] (44.97) \end{split}$$

$$F_2(x,y) = -(y-1-x)F_1\left(\frac{x}{y-1-x}, \frac{y}{y-1-x}\right)$$
(44.98)

and

$$\begin{split} F_3(x,y) = & \frac{1}{x(y-1-x)} \left[1 + 2x + 3x^2 + 2x^3 + x^4 \right. \\ & \left. -2y(1+x^3) + 3y^2(1+x^2) - 2y^3(1+x) + y^4 \right]. (44.99) \end{split}$$

These formulae must then be multiplied by the graviton density of states formula $dN=S_{n-1}\frac{M_{Pl}^2}{M_{r}^{n+2}}m^{n-1}dm$ to gain the cross section

$$\frac{d^2\sigma}{dtdm} = S_{n-1} \frac{M_{Pl}^2}{M_*^{n+2}} m^{n-1} \frac{d\sigma_m}{dt}$$
 (44.100)

where $S_n = \frac{(2\pi)^{n/2}}{\Gamma(n/2)}$ is the surface area of an *n*-dimensional sphere of

Virtual graviton processes can also be searched for at colliders. For instance, in Ref. [24] the cross section for Drell-Yan production of lepton pairs via gluon fusion was calculated, where it is found that, in the center-of-mass system

$$\frac{d\sigma}{dz}(gg \to \ell^+\ell^-) = \frac{\lambda^2 s^3}{64\pi M^8} (1 - z^2)(1 + z^2)$$
(44.101)

where $z=\cos\theta$ and λ is a model-dependent coupling constant ~ 1 . Formulae for Drell-Yan production via $q\bar{q}$ fusion can also be found in Ref. [24,25].

44.11. Warped extra dimensions

In the Randall-Sundrum model [26] of warped extra dimensions, the arena for physics is a 5-d anti-deSitter (AdS_5) spacetime, for which a non-factorizable metric exists with a metric warp factor $e^{-2\sigma(\phi)}$. It is assumed that two opposite tension 3-branes exist within AdS_5 at the two ends of an S_1/Z_2 orbifold parametrized by co-ordinate ϕ which runs from $0-\pi$. The 4-D solution of the Einstein equations yields $\sigma(\phi) = kr_c|\phi|$, where r_c is the compactification radius of the extra dimension and $k \sim M_{Pl}$. The 4-D effective action allows one to identify $\overline{M}_{Pl}^2 = \frac{M^3}{k}(1-e^{-2kr_c\pi})$, where M is the 5-D Planck scale. Physical particles on the TeV scale (SM) brane have mass $m = e^{-kr_c\pi}m_0$, where m_0 is a fundamental mass of order the Planck scale. Thus, the weak scale-Planck scale hierarchy occurs due to the existence of the exponential warp factor if $kr_c \sim 12$.

In the simplest versions of the RS model, the TeV-scale brane contains only SM particles plus a tower of KK gravitons. The RS gravitons have mass $m_n=kx_ne^{-kr_c\pi}$, where the x_i are roots of Bessel functions $J_1(x_n)=0$, with $x_1\simeq 3.83,\,x_2\simeq 7.02$ etc. While the RS zero-mode graviton couplings suppressed by $1/\overline{M}_{Pl}$ and are thus inconsequential for collider searches, the n=1 and higher modes have couplings suppressed instead by $\Lambda_\pi=e^{-kr_c\pi}\overline{M}_{Pl}\sim TeV$. The n=1 RS graviton should have width $\Gamma_1=\rho m_1x_1^2(k/\overline{M}_{Pl})^2$, where ρ is a constant depending on how many decay modes are open. The formulae for dilepton production via virtual RS graviton exchange can be gained from the above formulae for the ADD scenario via the replacement [27]

$$\frac{\lambda}{M_*^4} \to \frac{i^2}{8\Lambda_\pi^2} \sum_{n=1}^\infty \frac{1}{s - m_n^2 + i m_n \Gamma_n}.$$

45. NEUTRINO CROSS SECTION MEASUREMENTS

Written in April 2012 by G.P. Zeller (Fermilab).

Neutrino interaction cross sections are an essential ingredient in most neutrino experiments. Interest in neutrino scattering has recently increased due to the need for such information in the interpretation of neutrino oscillation data. Scattering results on both charged current (CC) and neutral current (NC) neutrino channels have been collected over many decades using a variety of targets, analysis techniques, and detector technologies. With the advent of intense neutrino sources for oscillation measurements, experiments are remeasuring these cross sections with a renewed appreciation for nuclear effects† and precise knowledge of their incoming neutrino fluxes. This review summarizes accelerator-based neutrino cross section measurements made in the $\sim 0.1-300$ GeV range with an emphasis on inclusive, quasi-elastic, and single pion production processes (areas where we have the most experimental input at present). For a more comprehensive discussion of neutrino interaction cross sections, including neutrino-electron scattering and lower energy measurements, the reader is directed to a recent review of this subject [1].

by NuTeV [2] and at lower energies on argon by ArgoNeuT [3]. At high energy, the inclusive cross section is dominated by deep inelastic scattering (DIS). Several high energy neutrino experiments have measured the DIS cross sections for specific final states, for example opposite-sign dimuon production. The most recent dimuon cross section measurements include those from CHORUS [4], NOMAD [5], and NuTeV [6]. At lower neutrino energies, the inclusive cross section is largely a combination of quasi-elastic scattering and resonance production processes, two areas we will turn to next.

45.2. Quasi-elastic scattering

Historically, neutrino (or antineutrino) quasi-elastic scattering refers to the processes, $\nu_{\mu} n \to \mu^{-} p$ and $\overline{\nu}_{\mu} p \to \mu^{+} n$, where a charged lepton and single nucleon are ejected in the elastic interaction of a neutrino (or antineutrino) with a nucleon in the target material. This is the final state one would strictly observe, for example, in scattering off of a free nucleon target. QE scattering is important as it is the dominant neutrino interaction at energies less than about 1 GeV and is a large signal sample in many neutrino oscillation experiments.

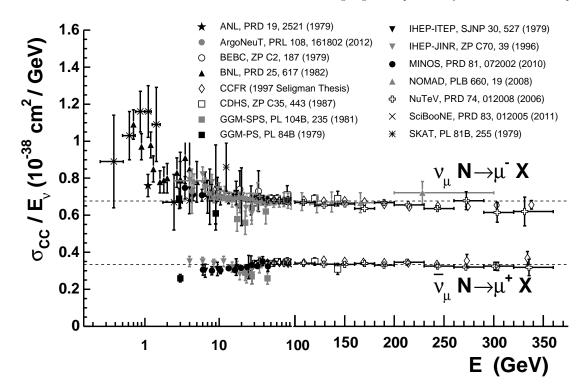

Fig. 45.1: Measurements of ν_{μ} and $\overline{\nu}_{\mu}$ CC inclusive scattering cross sections divided by neutrino energy as a function of neutrino energy. Note the transition between logarithmic and linear scales occurring at 100 GeV. Neutrino-nucleon cross sections are typically twice as large as the corresponding antineutrino cross sections, though this difference can be larger at lower energies. NC cross sections (not shown) are generally smaller (but non-negligible) compared to their CC counterparts.

45.1. Inclusive Scattering

Over the years, many experiments have measured the total cross section for neutrino $(\nu_{\mu} N \to \mu^{-} X)$ and antineutrino $(\overline{\nu}_{\mu} N \to \mu^{+} X)$ scattering off nucleons covering a broad range of energies (Fig. 45.1). As can be seen, the inclusive cross section approaches a linear dependence on neutrino energy. Such behavior is expected for point-like scattering of neutrinos from quarks, an assumption which breaks down at lower energies.

To provide a more complete picture, differential cross sections for such inclusive scattering processes have also been reported on iron

Fig. 45.2 displays the current status of existing measurements of ν_{μ} and $\overline{\nu}_{\mu}$ QE scattering cross sections as a function of neutrino energy. In this plot, and all others in this review, the prediction from a representative neutrino event generator (NUANCE) [7] provides a theoretical comparator. Other generators and more sophisticated calculations exist which can give different predictions [8].

In many of these initial measurements of the neutrino QE cross section, bubble chamber experiments typically employed light targets $(H_2 \text{ or } D_2)$ and required both the detection of the final state muon and single nucleon‡; thus the final state was clear and elastic kinematic conditions could be verified. The situation is more complicated of course for heavier nuclear targets. In this case, nuclear effects can

[†] Kinematic and final state effects which impact neutrino scattering off nuclei. Note that most modern neutrino experiments use nuclear targets to increase their event yields.

 $[\]ddagger$ In the case of D_2 , many experiments additionally observed the spectator proton.

impact the size and shape of the cross section as well as the final state kinematics and topology. Due to intranuclear rescattering and the possible effects of correlations between target nucleons, additional nucleons may be ejected in the final state; hence, a QE interaction on a nuclear target does not always imply the ejection of a single nucleon. Thus, one needs to take some care in defining what one means by neutrino QE scattering when scattering off targets heavier than H_2 or D_2 . Adding to the complexity, recent measurements [9] of the ν_{μ} QE scattering cross section on carbon at low energy have observed a significantly larger than expected cross section, an enhancement believed to be signaling the presence of sizable nuclear effects. Such cross sections have also been reported for the first time in the form of double-differential distributions [9], thus reducing the model-dependence of the data and allowing a much more stringent test of the underlying nuclear theory. The impact of nuclear effects on neutrino QE scattering has been the subject of intense theoretical scrutiny over the past year [19] with potential implications on nucleon ejection [20], neutrino energy reconstruction [21], and the neutrino/antineutrino cross section ratio [22]. The reader is referred to a recent review of the situation in [23]. Additional measurements are clearly needed before a complete understanding is achieved. In addition to such CC investigations, measurements of the NC counterpart of this channel have also been performed. The most recent NC elastic scattering cross section measurements include those from BNL E734 [24] and MiniBooNE [25]. A number of measurements of the Cabibbo-suppressed antineutrino QE hyperon production cross section have additionally been reported [18,26], although none in recent years.

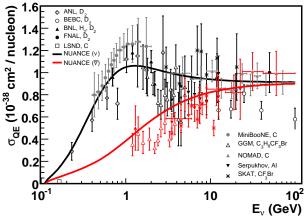

Figure 45.2: Measurements of ν_{μ} (black) and $\overline{\nu}_{\mu}$ (red) quasielastic scattering cross sections (per nucleon) as a function of neutrino energy. Data on a variety of nuclear targets are shown, including measurements from ANL [10], BEBC [11], BNL [12], FNAL [13], Gargamelle [14], LSND [15], MiniBooNE [9], NOMAD [16], Serpukhov [17], and SKAT [18]. Also shown is the QE free nucleon scattering prediction [7] assuming $M_A=1.0$ GeV. This prediction is significantly altered by nuclear corrections in the case of neutrino-nucleus scattering. Care should be taken in interpreting measurements on targets heavier than deuterium.

45.3. Pion Production

In addition to such elastic processes, neutrinos can also inelastically scatter producing a nucleon excited state (Δ , N^*). Such baryonic resonances quickly decay, most often to a nucleon and single pion final state. Fig. 45.3 and Fig. 45.4 show a collection of resonance single pion production cross section data for both CC and NC neutrino scattering. Decades ago, BEBC, FNAL, Gargamelle, and SKAT also performed similar measurements for antineutrinos [27]. Most often these experiments reported measurements of NC/CC single pion cross section ratios [28].

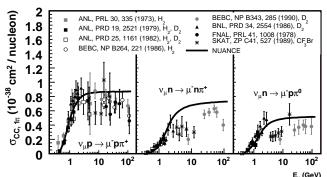

Figure 45.3: Historical measurements of ν_{μ} CC resonant single pion production. The data appear as reported by the experiments; no additional corrections have been applied to account for differing nuclear targets or invariant mass ranges. The free scattering prediction is from [7] with $M_A=1.1$ GeV. Note that other absolute measurements have been made by MiniBooNE [30] but cannot be directly compared with this historical data - the modern measurements are more inclusive and have quantified the production of pions leaving the target nucleus rather than specific $\pi+N$ final states as identified at the neutrino interaction vertex.

It should be noted that baryonic resonances can also decay to multi-pion, other mesonic $(K, \eta, \rho, \text{ etc.})$, and even photon final states. Experimental results for these channels are typically sparse or non-existent [1]; however, photon production processes can be an important background for $\nu_{\mu} \rightarrow \nu_{e}$ appearance searches and thus have become the focus of some recent experimental investigations [29].

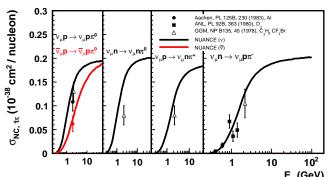

Figure 45.4: Same as Fig. 45.3 but for NC neutrino (black) and antineutrino (red) scattering. The Gargamelle measurements come from a re-analysis of this data [31]. Note that more recent absolute measurements exist [32] but cannot be directly compared with this data for the same reasons as in Fig. 45.3.

In addition to resonance production processes, neutrinos can also coherently scatter off of the entire nucleus and produce a distinctly forward-scattered single pion final state. Both CC ($\nu_{\mu}A \rightarrow \mu^{-}A\pi^{+}$, $\overline{\nu}_{\mu}A \rightarrow \mu^{+}A\pi^{-}$) and NC ($\nu_{\mu}A \rightarrow \nu_{\mu}A\pi^{0}$, $\overline{\nu}_{\mu}A \rightarrow \overline{\nu}_{\mu}A\pi^{0}$) processes are possible in this case. The level of coherent pion production is predicted to be small compared to incoherent processes [33], but observations exist across a broad energy range and on multiple nuclear targets [34–36]. Most of these measurements have been performed at energies above 2 GeV, but several modern experiments have started to search for coherent pion production at lower neutrino energies, including K2K [37], MiniBooNE [38], and SciBooNE [39].

As with QE scattering, a new appreciation for the significance of nuclear effects has surfaced in pion production channels, again due to the use of heavy targets in modern neutrino experiments. Many experiments have been careful to report cross sections for various detected final states, thereby not correcting for large and uncertain nuclear effects (e.g., pion rescattering, charge exchange, and absorption) which can introduce unwanted sources of uncertainty and

model dependence. Recent measurements of single pion cross sections, as published by K2K [40], MiniBooNE [41], and SciBooNE [42], take the form of ratios with respect to QE or CC inclusive scattering samples. Providing the most comprehensive survey of neutrino single pion production to date, MiniBooNE has recently published a total of 16 single- and double-differential cross sections for both the final state muon (in the case of CC scattering) and pion in these interactions; thus, providing the first measurements of these distributions [30,32]. Regardless of the interaction channel, such differential cross section measurements (in terms of observed final state particle kinematics) are now preferred for their reduced model dependence and for the additional kinematic information they provide. Such a new direction has been the focus of modern measurements as opposed to the reporting of (model-dependent) cross sections as a function of neutrino energy. Together with similar results for other interaction channels, a better understanding and modeling of nuclear effects will be possible moving forward.

45.4. Outlook

Coming soon, additional neutrino and antineutrino cross section measurements in the few-GeV energy range are anticipated from ArgoNeuT, MiniBooNE, MINOS, NOMAD, and SciBooNE. In addition, a few new experiments are now collecting data or will soon be commissioning their detectors. Analysis of a broad energy range of data on a variety of targets in the MINER ν A experiment will provide the most detailed analysis yet of nuclear effects in neutrino interactions. Data from ICARUS and MicroBooNE will probe deeper into complex neutrino final states using the superior capabilities of liquid argon time projection chambers, while the T2K and NOvA near detectors will collect high statistics samples in intense neutrino beams. Together, these investigations should significantly advance our understanding of neutrino-nucleus scattering in the years to come.

46. PLOTS OF CROSS SECTIONS AND RELATED QUANTITIES

(For neutrino plots, see review article "Neutrino Cross Section Measurements" by G.P. Zeller in this edition of RPP)

Jet Production in pp and $\overline{p}p$ Interactions

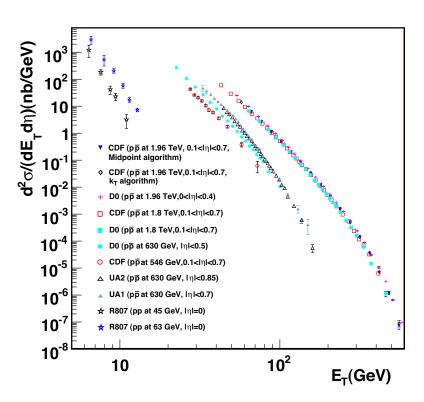

Figure 46.1: Inclusive differential jet cross sections plotted as a function of the jet tranverse energy. The CDF and D0 measurements use a cone algorithm of radius 0.7 for all results shown except for the CDF measurements at 1.96 TeV which also use k_T with a D parameter of 0.7 and midpoint algorithms. The cone/ k_T results should be similar if $R_{cone} = D$. UA1 (UA2) uses a non-iterative cone algorithm with a radius of 1.0 (1.3). Recent NLO QCD predictions (such as CTEQ6M) provide a good description of the CDF and D0 jet cross sections, Rept. on Prog. in Phys. 70, 89 (2007). Comparisons with the older cross sections are more difficult due to the nature of the jet algorithms used. CDF: Phys. Rev. D75, 092006 (2007), Phys. Rev. D64, 032001 (2001), Phys. Rev. Lett. 70, 1376 (1993); **D0**: Phys. Rev. **D64**, 032003 (2001); UA2: Phys. Lett. B257, 232 (1991); UA1: Phys. Lett. **B172**, 461 (1986); **R807**: Phys. Lett. B123, 133 (1983). (Courtesy of J. Huston, Michigan State University, 2010.)

Direct γ Production in $\overline{p}p$ Interactions

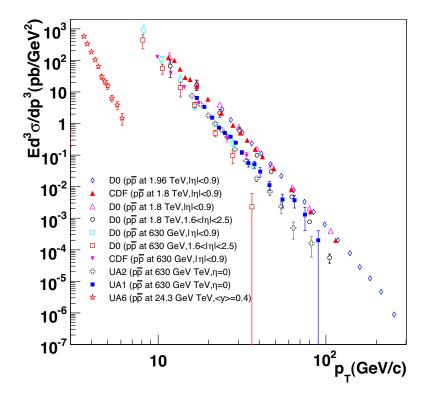

Figure 46.2: Isolated photon cross sections plotted as a function of the photon transverse momentum. The errors are either statistical only (CDF, D0 (1.96 TeV), UA1, UA2, UA6) or uncorrelated (D0 1.8 TeV, 630 GeV). The data are generally in good agreement with NLO QCD predictions, albeit with a tendency for the data to be above (below) the theory for lower (large) transverse momenta, Phys. Rev. D59, 074007 (1999). Do: Phys. Lett. B639, 151 (2006), Phys. Rev. Lett. 87, 251805 (2001); CDF: Phys. Rev. D65, 112003 (2002); UA6: Phys. Lett. B206, 163 (1988); **UA1**: Phys. Lett. **B209**, 385 (1988); **UA2**: Phys. Lett. **B288**, 386 (1992). (Courtesy of J. Huston, Michigan State University, 2007.)

Differential Cross Section for W and Z Boson Production

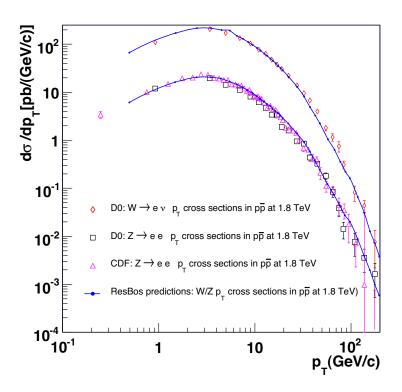

Figure 46.3: Differential cross sections for W and Z production shown as a function of the boson transverse momentum. The D0 results include only the statistical error while the CDF results include all errors except for the 3.9% integrated luminosity error. The results are in good agreement with theoretical predictions that include both the effects of NLO corrections and of q_T resummation, such as the ResBos (Phys. Rev. **D67**, 073016 (2003)) predictions indicated on the plot. D0: Phys. Lett. **B513**, 292 (2001), Phys. Rev. Lett. 84, 2792 (2000). CDF: Phys. Rev. Lett. 84, 845 (2000). (Courtesy of J. Huston, Michigan State University, 2007)

Pseudorapidity Distributions in $\overline{p}p$ Interactions

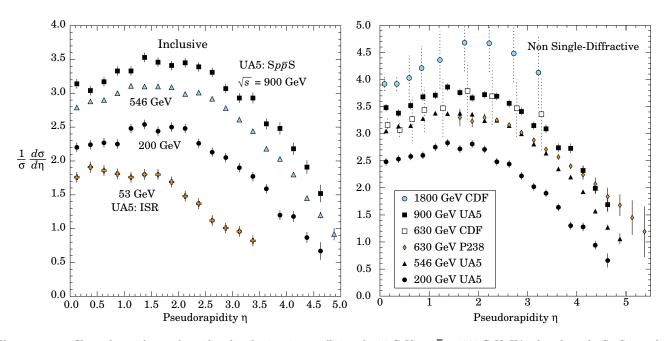

Figure 46.4: Charged particle pseudorapidity distributions in $p\overline{p}$ collisions for 53 GeV $\leq \sqrt{s} \leq$ 1800 GeV. UA5 data from the $Sp\overline{p}S$ are taken from G.J. Alner *et al.*, Z. Phys. **C33**, 1 (1986), and from the ISR from K. Alpgøard *et al.*, Phys. Lett. **112B**, 193 (1982). The UA5 data are shown for both the full inelastic cross section and with singly diffractive events excluded. Additional non single-diffractive measurements are available from CDF at the Tevatron, F. Abe *et al.*, Phys. Rev. **D41**, 2330 (1990) and Experiment P238 at the $Sp\overline{p}S$, R. Harr *et al.*, Phys. Lett. **B401**, 176 (1997). (Courtesy of D.R. Ward, Cambridge Univ., 1999)

Average Hadron Multiplicities in Hadronic e^+e^- Annihilation Events

Table 46.1: Average hadron multiplicities per hadronic e^+e^- annihilation event at $\sqrt{s}\approx 10,\,29-35,\,91,\,$ and 130–200 GeV. The rates given include decay products from resonances with $c\tau<10$ cm, and include the corresponding anti-particle state. Correlations of the systematic uncertainties were considered for the calculation of the averages. (Updated May 2010 by O. Biebel, LMU, Munich)

Notes for Table 46.1:

- (a) $\sigma_{\rm had} = 3.33 \pm 0.05 \pm 0.21$ nb (CLEO: Phys. Rev. **D29**, 1254 (1984)) has been used in converting the measured cross sections to average hadron multiplicities.
- (b) $B(D_s \to \eta \pi, \eta' \pi)$ was used (RPP 1994).
- (c) Comprises both charged and neutral B meson states.
- (d) The Standard Model $B(Z \to b\overline{b}) = 0.217$ was used.
- (e) $x_p = p/p_{\text{beam}} > 0.1$ only.
- (f) Both charge states.
- (g) $B(D^*(2010)^+ \to D^0\pi^+) \times B(D^0 \to K^-\pi^+)$ has been used (RPP 2000).
- (h) $B(D_s^* \to D_S^+ \gamma)$, $B(D_s^+ \to \phi \pi^+)$, $B(\phi \to K^+ K^-)$ have been used (RPP 1998).
- (i) Any charge state (i.e., B_d^* , B_u^* , or B_s^*).
- (j) $B(Z \rightarrow hadrons) = 0.699$ was used (RPP 1994).
- (k) Any charge state (i.e., B_d^{**} , B_u^{**} , or B_s^{**}).
- (ℓ) Assumes B($D_{s1}^+ \to D^{*+}K^0 + D^{*0}K +) = 100\%$ and B($D_{s2}^+ \to D^0K^+) = 45\%$.
- (m) The value was derived from the cross section of $\Lambda_c^+ \to p\pi K$ using (a) and assuming the branching fraction to be $(5.0 \pm 1.3)\%$ (RPP 2004).

Average e^+e^- , pp, and $\overline{p}p$ Multiplicity

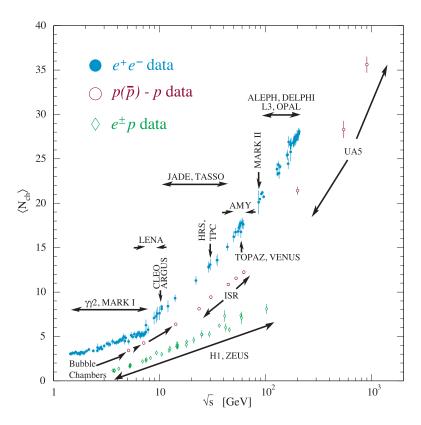

Figure 46.5: Average multiplicity as a function of \sqrt{s} for e^+e^- and $p\overline{p}$ annihilations, and pp and ep collisions. The indicated errors are statistical and systematic errors added in quadrature, except when no systematic errors are given. Files of the data shown in this figure are given in http://pdg.lbl.gov/current/avg-multiplicity/.

 e^+e^- : Most e^+e^- measurements include contributions from K_S^0 and Λ decays. The $\gamma\gamma 2$ and MARK I measurements contain a systematic 5% error. Points at identical energies have been spread horizontally for clarity:

σ and R in e^+e^- Collisions

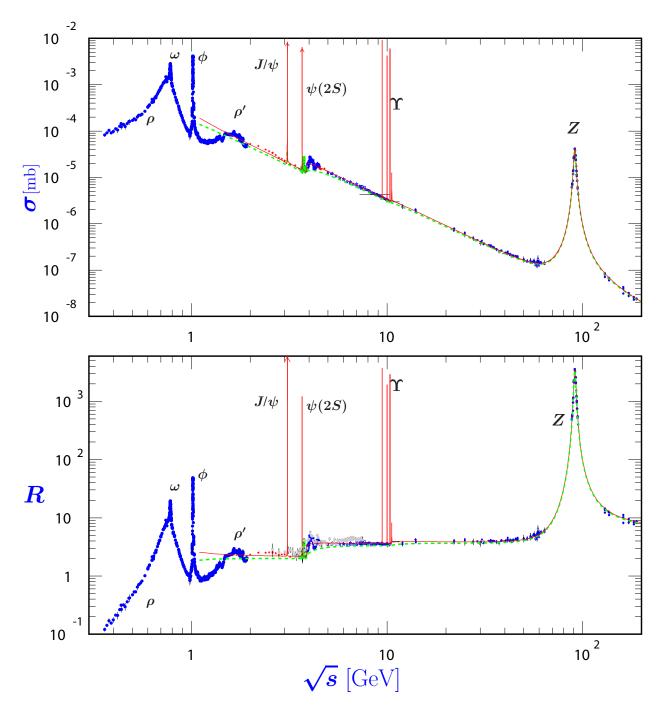

Figure 46.6: World data on the total cross section of $e^+e^- \to hadrons$ and the ratio $R(s) = \sigma(e^+e^- \to hadrons, s)/\sigma(e^+e^- \to \mu^+\mu^-, s)$. $\sigma(e^+e^- \to hadrons, s)$ is the experimental cross section corrected for initial state radiation and electron-positron vertex loops, $\sigma(e^+e^- \to \mu^+\mu^-, s) = 4\pi\alpha^2(s)/3s$. Data errors are total below 2 GeV and statistical above 2 GeV. The curves are an educative guide: the broken one (green) is a naive quark-parton model prediction, and the solid one (red) is 3-loop pQCD prediction (see "Quantum Chromodynamics" section of this *Review*, Eq. (9.7) or, for more details, K. G. Chetyrkin *et al.*, Nucl. Phys. **B586**, 56 (2000) (Erratum *ibid.* **B634**, 413 (2002)). Breit-Wigner parameterizations of J/ψ , $\psi(2S)$, and $\Upsilon(nS)$, n=1,2,3,4 are also shown. The full list of references to the original data and the details of the R ratio extraction from them can be found in [arXiv:hep-ph/0312114]. Corresponding computer-readable data files are available at http://pdg.lbl.gov/current/xsect/. (Courtesy of the COMPAS (Protvino) and HEPDATA (Durham) Groups, May 2010.)

R in Light-Flavor, Charm, and Beauty Threshold Regions

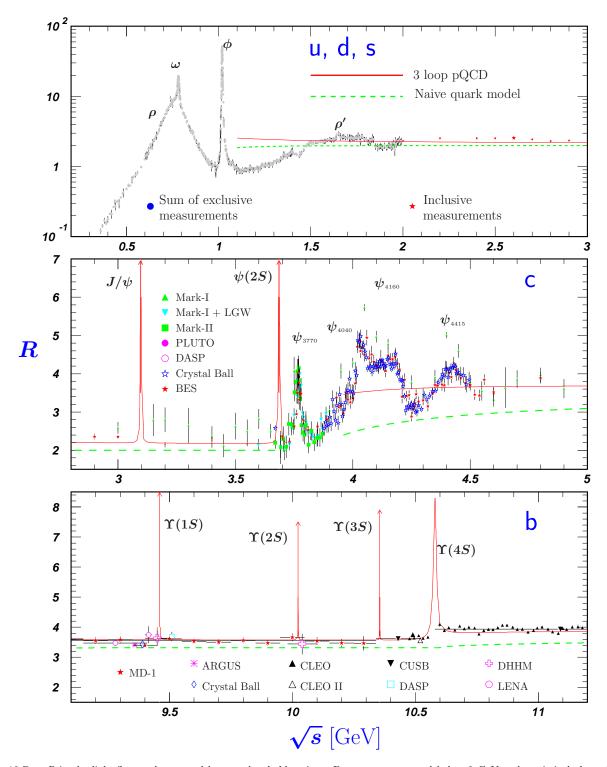

Figure 46.7: R in the light-flavor, charm, and beauty threshold regions. Data errors are total below 2 GeV and statistical above 2 GeV. The curves are the same as in Fig. 46.6. Note: CLEO data above $\Upsilon(4S)$ were not fully corrected for radiative effects, and we retain them on the plot only for illustrative purposes with a normalization factor of 0.8. The full list of references to the original data and the details of the R ratio extraction from them can be found in <code>[arXiv:hep-ph/0312114]</code>. The computer-readable data are available at http://pdg.lbl.gov/current/xsect/. (Courtesy of the COMPAS (Protvino) and HEPDATA (Durham) Groups, May 2010.)

Annihilation Cross Section Near M_Z

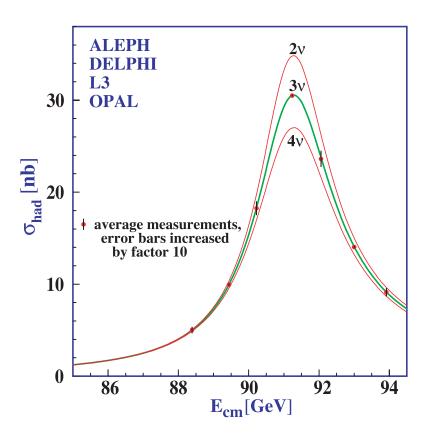

Figure 46.8: Combined data from the ALEPH, DELPHI, L3, and OPAL Collaborations for the cross section in e^+e^- annihilation into hadronic final states as a function of the center-of-mass energy near the Z pole. The curves show the predictions of the Standard Model with two, three, and four species of light neutrinos. The asymmetry of the curve is produced by initial-state radiation. Note that the error bars have been increased by a factor ten for display purposes. References:

Table 46.2: Total hadronic cross section. Analytic S-matrix and Regge theory suggest a variety of parameterizations of total cross sections at high energies with different areas of applicability and fits quality.

A ranking procedure, based on measures of different aspects of the quality of the fits to the current evaluated experimental database, allows one to single out the following parameterization of highest rank [1]

$$\sigma^{ab} = Z^{ab} + B^{ab} \log^2(s/s_M) + Y_1^{ab} (s_M/s)^{\eta_1} - Y_2^{ab} (s_M/s)^{\eta_2} \qquad \sigma^{\overline{a}b} = Z^{ab} + B^{ab} \log^2(s/s_M) + Y_1^{ab} (s_M/s)^{\eta_1} + Y_2^{ab} (s_M/s)^{\eta_2} \ ,$$

where Z^{ab} , $B^{a(p,n,\gamma*)} = \pi \frac{(\hbar c)^2}{M^2}$, $B^{ad} = \lambda \pi \frac{(\hbar c)^2}{M^2}$ (dimensionless factor λ introduced to test the universality for nuclei targets), Y_i^{ab} are in mb; s, $s_M = (m_a + m_b + M)^2$ are in GeV²; m_a , m_b , $[m_{\gamma^*} = m_{\rho(770)}]$ are the masses of initial state particles, and M – the mass parameter defining the rate of universal rise of the cross sections are all in GeV. Parameters M, η_1 and η_2 are universal for all collisions considered. Terms $Z^{ab} + B^{ab} \log^2(s/s_M)$ represent the pomerons. The exponents η_1 and η_2 represent lower-lying C-even and C-odd exchanges, respectively. In addition to total cross sections σ , the measured ratios of the real-to-imaginary parts of the forward scattering amplitudes $\rho = Re(T)/Im(T)$ are included in the fits by using s to u crossing symmetry and differential dispersion relations.

Exact factorization hypothesis was used for both Z^{ab} and $B^{ab}\log^2(s/s_M)$ to extend the universal rise of the total hadronic cross sections to the $\gamma p \to hadrons$ and $\gamma \gamma \to hadrons$ collisions. This results in substitutions: $Z^{\gamma p} + \pi \frac{(\hbar c)^2}{M^2}\log^2(s/s_M) \Rightarrow \delta[Z^{pp} + \pi \frac{(\hbar c)^2}{M^2}\log^2(s/s_M)]$, and $Z^{\gamma \gamma} + \pi \frac{(\hbar c)^2}{M^2}\log^2(s/s_M) \Rightarrow \delta^2[Z^{pp} + \pi \frac{(\hbar c)^2}{M^2}\log^2(s/s_M)]$, with the additional parameter δ . Simultaneous fit was made to the 2011-updated data for all collisions listed in the central column of the table. The total number of adjusted parameters is **34**. Asymptotic parameters $(Z, M, \lambda, \delta, \eta_1, \eta_2)$ thus obtained were then fixed and used as inputs to fits by groups to check a stability of the whole situation with description of the high energy data. Results are shown in the right hand part of the table. All fits included data above $\sqrt{s_{\min}} = 5$ GeV with overall $\chi^2/\text{dof} = 0.96$.

The fitted functions are shown in the following figures, along with one-standard-deviation error bands. Whenever the reduced χ^2 is greater than one, a scale factor has been included to evaluate the parameter values and to draw the error bands. Where appropriate, statistical and systematic errors were combined quadratically in constructing weights for all fits. Only statistical error bars are shown on the plots. Vertical arrows indicate lower limits on the $p_{\rm lab}$ or \sqrt{s} range used in the fits. Database used in the fits now includes pp data from TOTEM experiment [2] and new data in the RHIC energy range from ARGO-YBJ cosmic ray experiment [3]. The modifications of the universal asymptotic term are motivated by ideas, suggestions and results from the old and recent papers [4-13]. Computer-readable data files are available at http://pdg.lbl.gov/current/xsect/. (Courtesy of the COMPAS group, IHEP, Protvino, April 2012)

 $^{
m 1}$ RYUTOV 07 extends the method of RYUTOV 97 to the radius of Pluto's orbit. ² ACCIOLY 10 limits come from possible alterations of anomalous magnetic moment of electron and gravitational deflection of electromagnetic radiation. Reported limits are not "claimed" by the authors and in any case are not competitive.

not "claimed" by the authors and in any case are not competitive. 3 When trying to measure m one must distinguish between measurements performed on large and small scales. If the photon acquires mass by the Higgs mechanism, the large-scale behavior of the photon might be effectively Maxwellian. If, on the other hand, one postulates the Proca regime for all scales, the very existence of the galactic field implies $m<10^{-26}$ eV, as correctly calculated by YAMAGUCHI 59 and CHIBISOV 76.
4 LUO 03 determine a limit on $\mu^2~A<1.1\times10^{-11}~T~m/m^2$ (with μ^{-1} =characteristic length for photon mass; A=ambient vector potential) — similar to the LAKES 98 technique. Unlike LAKES 98 who used static, the authors used dynamic torsion balance. Assuming A to be $10^{12}~T~m$, they obtain $\mu < 1.2\times10^{-51}~g$, equivalent to $6.7\times10^{-19}~eV$. The rotating modified Cavendish balance removes dependence on the direction of A. GOLDHABER 03 argue that because plasma current effects are neglected, the LUO 03 GOLDHABER 03 argue that because plasma current effects are neglected, the LUO 03 limit does not provide the best available limit on μ^2 A nor a reliable limit at all on μ .

limit does not provide the best available limit on $\mu^2 A$ nor a reliable limit at all on μ . The reason is that the A associated with cluster magnetic fields could become arbitrarily small in plasma voids, whose existence would be compatible with present knowledge. LUO 03B reply that fields of distant clusters are not accurately mapped, but assert that a zero A is unlikely given what we know about the magnetic field in our galaxy. LAKES 98 reports limits on torque on a toroid Cavendish balance, obtaining a limit on $\mu^2 A < 2 \times 10^{-9} \, \text{Tm/m}^2$ via the Maxwell-Proca equations, where μ^{-1} is the characteristic length associated with the photon mass and A is the ambient vector potential in the Lorentz gauge. Assuming $A \approx 1 \times 10^{12} \, \text{Tm}$ due to cluster fields he obtains $\mu^{-1} > 2 \times 10^{10} \, \text{m}$, corresponding to $\mu < 1 \times 10^{-17} \, \text{eV}$. A more conservative limit, $\mu = 1 \times 10^{12} \, \text{cm}$ has $\mu = 1 \times 10^{12} \, \text{cm}$. using $A\approx (1~\mu{\rm G})\times (600~{\rm pc})$ based on the galactic field, is $\mu^{-1}>1\times 10^9~{\rm m}$ or $\mu<2\times 10^{-16}~{\rm eV}.$

6 RYUTOV 97 uses a magnetohydrodynamics argument concerning survival of the Sun's field to the radius of the Earth's orbit. "To reconcile observations to theory, one has to reduce [the photon mass] by approximately an order of magnitude compared with"

KROLL 71. See also review GOLDHABER 71B.

γ CHARGE

OKUN 06 has argued that schemes in which all photons are charged are inconsistent. He says that if a neutral photon is also admitted to avoid this problem, then other problems emerge, such as those connected with the emission and absorption of charged photons by charged particles. He concludes that in the absence of a self-consistent phenomenological basis, interpretation of experimental data is at best difficult.

J = 1

THE MASS AND WIDTH OF THE W BOSON

Revised March 2012 by M.W. Grünewald (U Ghent) and A. Gurtu (King Abdulaziz University).

Precision determination of the W-mass is of great importance in testing the internal consistency of the Standard Model and, together with other electroweak data, in constraining the mass of the undiscovered Higgs boson. From the time of its discovery in 1983, the W-boson has been studied and its mass determined in $p\bar{p}$ and e^+e^- interactions; it is currently studied in pp interactions at the LHC. The W mass and width definition used here corresponds to a Breit-Wigner with mass-dependent width.

Production of on-shell W bosons at hadron colliders is tagged by the high p_T charged lepton from its decay. Owing to the unknown parton-parton effective energy and missing energy in the longitudinal direction, the collider experiments reconstruct the transverse mass of the W, and derive the W mass from comparing the transverse mass distribution with Monte Carlo predictions as a function of M_W . These analyses use the electron and muon decay modes of the W boson.

In the e^+e^- collider (LEP) a precise knowledge of the beam energy enables one to determine the $e^+e^- \rightarrow W^+W^-$ cross section as a function of center of mass energy, as well as

to reconstruct the W mass precisely from its decay products, even if one of them decays leptonically. Close to the W⁺W⁻ threshold (161 GeV), the dependence of the W-pair production cross section on M_W is large, and this was used to determine M_W . At higher energies (172 to 209 GeV) this dependence is much weaker and W-bosons were directly reconstructed and the mass determined as the invariant mass of its decay products, improving the resolution with a kinematic fit.

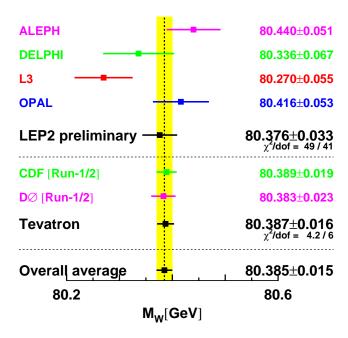

Figure 1: Measurements of the W-boson mass by the LEP and Tevatron experiments.

In order to compute the LEP average W mass, each experiment provided its measured W mass for the $q\overline{q}q\overline{q}$ and $q\overline{q}\ell\overline{\nu_\ell},~\ell=e,\mu,\tau$ channels at each center-of-mass energy, along with a detailed break-up of errors: statistical, uncorrelated, partially correlated and fully correlated systematics [1]. These have been combined to obtain a LEP W mass of $M_W=80.376\pm0.033~{\rm GeV}$. Errors due to uncertainties in LEP energy (9 MeV), and possible effect of color reconnection (CR) and Bose-Einstein correlations (BEC) between quarks from different W's (8 MeV) are included. The mass difference between $q\overline{q}q\overline{q}$ and $q\overline{q}\ell\overline{\nu_\ell}$ final states (due to possible CR and BEC effects) is $-12\pm45~{\rm MeV}$. In a similar manner, the width results obtained at LEP have been combined, resulting in $\Gamma_W=2.196\pm0.083~{\rm GeV}$ [1].

The two Tevatron experiments have also identified common systematic errors. Between the two experiments, uncertainties due to the parton distribution functions, radiative corrections, and choice of mass (width) in the width (mass) measurements are treated as correlated. An average W mass of $M_W=80.420\pm0.031~{\rm GeV}$ [2] and a W width of $\Gamma_W=2.046\pm0.049~{\rm GeV}$ [3] are obtained. Errors of 12 MeV (20 MeV) and 9 MeV (7 MeV) accounting for PDF and radiative correction

²FINN 02 analyze the orbital decay rates of PSR B1913+16 and PSR B1534+12 with a possible graviton mass as a parameter. The combined frequentist mass limit is at 90%CL.

³DAMOUR 91 is an analysis of the orbital period change in binary pulsar PSR 1913+16, and confirms the general relativity prediction to 0.8%. "The theoretical importance of the [rate of orbital period decay] measurement has long been recognized as a direct confirmation that the gravitational interaction propagates with velocity c (which is the immediate cause of the appearance of a damping force in the binary pulsar system) and thereby as a test of the existence of gravitational radiation and of its quadrupolar nature." TAYLOR 93 adds that orbital parameter studies now agree with general relativity to 0.5%, and set limits on the level of scalar contribution in the context of a family of

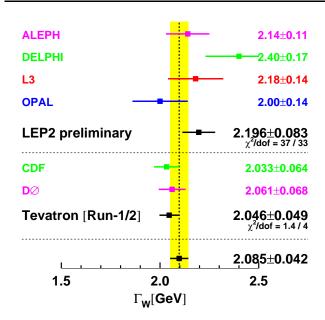

Figure 2: Measurements of the W-boson width by the LEP and Tevatron experiments.

uncertainties in the mass (width) combination dominate the correlated uncertainties.

At the 2012 winter conferences, the CDF and D0 experiments have presented new results for the mass of the W boson based on $2-4~{\rm fb^{-1}}$ of Run-II data, $80.387\pm0.019~{\rm GeV}$ [4] and $80.375\pm0.023~{\rm GeV}$ [5], respectively. The W-mass determination from the Tevatron experiments has thus become very precise. Combining all Tevatron results from Run-I and Run-II using an improved treatment of correlations, a new average of $80.387\pm0.016~{\rm GeV}$ is obtained [6], with common uncertainties of 10 MeV (PDF) and 4 MeV (radiative corrections).

The LEP and Tevatron results on mass and width, which are based on all results available, are compared in Fig. 1 and Fig. 2. Good agreement between the results is observed. Combining these results, assuming no common systematic uncertainties between the LEP and the Tevatron measurements, yields an average W mass of $M_W=80.385\pm0.015$ GeV and a W width of $\Gamma_W=2.085\pm0.042$ GeV.

The Standard Model prediction from the electroweak fit, using Z-pole data plus $m_{\rm top}$ measurement, gives a W-boson mass of $M_W=80.365\pm0.020$ GeV and a W-boson width of $\Gamma_W=2.091\pm0.002$ GeV [7].

W MASS

The W-mass listed here corresponds to the mass parameter in a Breit-Wigner distribution with mass-dependent width. To obtain the world average, common systematic uncertainties between experiments are properly taken into account. The LEP-2 average W mass based on published results is 80.376 ± 0.033 GeV [CERN-PH-EP/2006-042]. The combined Tevatron data yields an average W mass of 80.387 ± 0.016 GeV [FERMILAB-TM-2532-EI.

 $\mbox{OUR}\mbox{ FIT}$ uses these average LEP and Tevatron mass values and combines them assuming no correlations.

 $^{^1}$ AALTONEN 12E select 470k $W\to e\nu$ decays and 625k $W\to \mu\nu$ decays in 2.2 fb $^{-1}$ of Run-II data. The mass is determined using the transverse mass, transverse lepton momentum and transverse missing energy distributions, accounting for correlations. This results superseeds AALTONEN 07F.

 $^{^2}$ ABAZOV 12F select 1677k $W\to e\nu$ decays in 4.3 fb $^{-1}$ of Run-II data. The mass is determined using the transverse mass and transverse lepton momentum distributions, accounting for correlations.

 $^{^3}$ ABAZOV 09AB study the transverse mass, transverse electron momentum, and transverse missing energy in a sample of 0.5 million $W \to e \nu$ decays selected in Run-II data. The quoted result combines all three methods, accounting for correlations.

 $^{^4}$ ABDALLAH 08a use direct reconstruction of the kinematics of $W^+W^-\to q\overline{q}\ell\nu$ and $W^+W^-\to q\overline{q}q\overline{q}$ events for energies 172 GeV and above. The W mass was also extracted from the dependence of the WW cross section close to the production threshold and combined appropriately to obtain the final result. The systematic error includes ± 0.025 GeV due to final state interactions and ± 0.009 GeV due to LEP energy uncertainty.

⁵ ABBIENDI 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\,\ell\nu_\ell$ and $W^+W^- \to q\overline{q}\,q\overline{q}$ events. The result quoted here is obtained combining this mass value with the results using $W^+W^- \to \ell\nu_\ell\ell^\ell\nu_{\ell^\prime}$ events in the energy range 183–207

W

GeV (ABBIENDI 03c) and the dependence of the WW production cross-section on m_W at threshold. The systematic error includes ± 0.009 GeV due to the uncertainty on the LEP beam energy.

- ⁶ ACHARD 06 use direct reconstruction of the kinematics of $W^+W^- \to q \overline{q} \ell \nu_\ell$ and $W^+W^- \to q \overline{q} q \overline{q}$ events in the C.M. energy range 189–209 GeV. The result quoted here is obtained combining this mass value with the results obtained from a direct W mass reconstruction at 172 and 183 GeV and with those from the dependence of the WW production cross-section on m_W at 161 and 172 GeV (ACCIARRI 99).
- 7 SCHAEL 06 use direct reconstruction of the kinematics of $W^+W^-\to q\overline{q}\,q\overline{q}$ events in the C.M. energy range 183–209 GeV. The result quoted here is obtained combining this mass value with those obtained from the dependence of the W pair production cross-section on m_V at 161 and 172 GeV (BARATE 97 and BARATE 97s respectively). The systematic error includes ± 0.009 GeV due to possible effects of final state interactions in the $q\overline{q}\,q\overline{q}$ channel and ± 0.009 GeV due to the uncertainty on the LEP beam energy.
- 8 ABAZOV 02D improve the measurement of the W-boson mass including $W \to e \nu_e$ events in which the electron is close to a boundary of a central electromagnetic calorimeter module. Properly combining the results obtained by fitting $m_T(W)$, $p_T(e)$, and $p_T(\nu)$, this sample provides a mass value of 80.574 \pm 0.405 GeV. The value reported here is a combination of this measurement with all previous DØ W-boson mass measurements.
- **Online of this measurement with an provided by the second control of the second contr
- 10 AALTONEN 07F obtain high purity $W\to e\nu_e$ and $W\to \mu\nu_\mu$ candidate samples totaling 63,964 and 51,128 events respectively. The W mass value quoted above is derived by simultaneously fitting the transverse mass and the lepton, and neutrino \mathbf{p}_T distributions.
- $^{11}\text{AKTAS}$ 06 fit the Q^2 dependence (300 $< Q^2 <$ 30,000 GeV 2) of the charged-current differential cross section with a propagator mass. The first error is experimental and the second corresponds to uncertainties due to input parameters and model assumptions.
- 12 CHEKA NOV 02c fit the Q^2 dependence (200< Q^2 <60000 GeV 2) of the charged-current differential cross sections with a propagator mass fit. The last error is due to the uncertainty on the probability density functions.
- $^{13}\,\mathrm{BREITWEG}$ 00D fit the Q^2 dependence (200 < Q^2 < 22500 GeV^2) of the charged-current differential cross sections with a propagator mass fit. The last error is due to the uncertainty on the probability density functions.
- 14 ALITTI 92B result has two contributions to the systematic error (\pm 0.83); one (\pm 0.81) cancels in m_W/m_Z and one (\pm 0.17) is noncancelling. These were added in quadrature. We choose the ALITTI 92B value without using the LEP m_Z value, because we perform our own combined fit.
- 15 There are two contributions to the systematic error (± 0.84) : one (± 0.81) which cancels in m_W/m_Z and one (± 0.21) which is non-cancelling. These were added in quadrature.
- $^{16}_{-}$ ABE 891 systematic error dominated by the uncertainty in the absolute energy scale.

W WIDTH

The W width listed here corresponds to the width parameter in a Breit-Wigner distribution with mass-dependent width. To obtain the world average, common systematic uncertainties between experiments are properly taken into account. The LEP-2 average W width based on published results is 2.196 ± 0.083 GeV [CERN-PH-EP/2006-042]. The combined Tevatron data yields an average W width of 2.046 ± 0.049 GeV [FERMILAB-TM-2460-E].

OUR FIT uses these average LEP and Tevatron width values and combines them assuming no correlations.

- 23 ABAZOV 09AK obtain this result fitting the high-end tail (100-200 GeV) of the transverse mass spectrum in $W\to~e\nu$ decays.
- ²⁴ AALTONEN 08e obtain this result fitting the high-end tail (90–200 GeV) of the transverse mass spectrum in semileptonic $W \rightarrow e \nu_e$ and $W \rightarrow \mu \nu_\mu$ decays.
- ²⁵ ABDALLAH 08a use direct reconstruction of the kinematics of $W^+W^-\to q\overline{q}\ell\nu$ and $W^+W^-\to q\overline{q}q\overline{q}$ events. The systematic error includes ± 0.065 GeV due to final state interactions.
- 26 ABBIENDI 06 use direct reconstruction of the kinematics of $W^+W^- \to q\overline{q}\,\ell\nu_\ell$ and $W^+W^- \to q\overline{q}\,q\overline{q}$ events. The systematic error includes ± 0.003 GeV due to the uncertainty on the LEP beam energy.
- 27 ACHARD 06 use direct reconstruction of the kinematics of $W^+W^-\to q\overline{q}\,\ell\nu_\ell$ and $W^+W^-\to q\overline{q}\,q\overline{q}$ events in the C.M. energy range 189–209 GeV. The result quoted here is obtained combining this value of the width with the result obtained from a direct W mass reconstruction at 172 and 183 GeV (ACCIARRI 99).
- 28 SCHAEL 06 use direct reconstruction of the kinematics of $W^+W^-\to q\overline{q}\,\ell\nu_\ell$ and $W^+W^-\to q\overline{q}\,q\overline{q}$ events. The systematic error includes ± 0.05 GeV due to possible effects of final state interactions in the $q\overline{q}\,q\overline{q}$ channel and ± 0.01 GeV due to the uncertainty on the LEP beam energy.
- 29 ABAZOV 02E obtain this result fitting the high-end tail (90–200 GeV) of the transverse-mass spectrum in semileptonic $W \rightarrow e \nu_e$ decays.
- 30 AFFOLDER 00M fit the high transverse mass (100–200 GeV) $W\to e\nu_e$ and $W\to \mu\nu_\mu$ events to obtain $\Gamma(W)=2.04\pm0.11({\rm stat})\pm0.09({\rm syst})$ GeV. This is combined with the earlier CDF measurement (ABE 95c) to obtain the quoted result.
- 31 ABBOTT 00B measure $R=10.43\pm0.27$ for the $W\to e\nu_e$ decay channel. They use the SM theoretical predictions for $\sigma(W)/\sigma(Z)$ and $\Gamma(W\to e\nu_e)$ and the world average for $B(Z\to ee)$. The value quoted here is obtained combining this result (2.169 \pm 0.070 GeV) with that of ABBOTT 99H.
- 32 ABE 95 w measured $R=10.90\pm0.32\pm0.29$. They use $m_{W}=80.23\pm0.18$ GeV, $\sigma(W)/\sigma(Z)=3.35\pm0.03$, $\Gamma(W\to e\nu)=225.9\pm0.9$ MeV, $\Gamma(Z\to e^+e^-)=83.98\pm0.18$ MeV, and $\Gamma(Z)=2.4969\pm0.0038$ GeV. 33 ALITTI 92 measured $R=10.4^{+0.7}_{-0.6}\pm0.3$. The values of $\sigma(Z)$ and $\sigma(W)$ come from
- 33 ALITTI 92 measured $R=10.4^{+0.7}_{-0.6}\pm0.3$. The values of $\sigma(Z)$ and $\sigma(W)$ come from $O(\alpha_S^2)$ calculations using $m_W=80.14\pm0.27$ GeV, and $m_Z=91.175\pm0.021$ GeV along with the corresponding value of $\sin^2\!\theta_W=0.2274$. They use $\sigma(W)/\sigma(Z)=3.26\pm0.07\pm0.05$ and $\Gamma(Z)=2.487\pm0.010$ GeV.
- 34 ALBAJAR 91 measured $R=9.5^{+}_{-1.0}^{+}$ (stat. + syst.). $\sigma(W)/\sigma(Z)$ is calculated in QCD at the parton level using $m_W=80.18\pm0.28$ GeV and $m_Z=91.172\pm0.031$ GeV along with $\sin^2\theta_W=0.2322\pm0.0014$. They use $\sigma(W)/\sigma(Z)=3.23\pm0.05$ and $\Gamma(Z)=2.498\pm0.020$ GeV. This measurement is obtained combining both the electron and muon channels.

W+ DECAY MODES

 36 BARATE 99L ALEP $E_{\mathrm{Cm}}^{ee} = 161 + 172 + 183~\mathrm{GeV}$

 35 BARATE 991 measure this quantity using the dependence of the total cross section σ_{WW} upon a change in the total width. The fit is performed to the WW measured cross sections at 161, 172, and 183 GeV. This partial width is < 139 MeV at 95%CL.

 36 BARATE 99L use W-pair production to search for effectively invisible W decays, tagging with the decay of the other W boson to Standard Model particles. The partial width for effectively invisible decay is < 27 MeV at 95%CL.

W BRANCHING RATIOS

Overall fits are performed to determine the branching ratios of the W. LEP averages on $W \to e \nu_e$, $W \to \mu \nu_\mu$, and $W \to \tau \nu_\tau$, and their correlations are first obtained by combining results from the four experiments taking properly into account the common systematics. The procedure is described in the note LEPEWWG/XSEC/2001-02, 30 March 2001, at http://lepewwg.web.cern.ch/LEPEWWG/lepew/4f/PDG01. The LEP average values so obtained, using published data, are given in the note LEPEWWG/SSEC/2005-01 accessible at http://lepewwg.web.cern.ch/LEPEWWG/lepew/4f/PDG05. These results, together with results from the $p\overline{p}$ colliders are then used in fits to obtain the world average W branching ratios. A first fit determines three individual leptonic branching ratios, $B(W \to e \nu_e)$, $B(W \to \mu \mu_\mu)$, and $B(W \to \tau \nu_\tau)$. This fit has a χ^2 =7.9 for 9 degrees of freedom. The correleation coefficients between the branching fractions are 0.08 $(e-\mu)$, -0.21 $(e-\tau)$, -0.14 $(\mu-\tau)$. A second fit assumes lepton universality and determines the leptonic branching ratio $B(W \to \ell \nu_\ell)$ and the hadronic branching ratio is derived as $B(W \to hadrons) = 1$ –3 $B(W \to \ell \nu)$. This fit has a χ^2 =15.5 for 11 degrees of freedom.

The LEP $W \rightarrow \ell \nu$ data are obtained by the Collaborations using individual leptonic channels and are, therefore, not included in the overall fits to avoid double counting

Note: The LEP combination including the new OPAL results, ABBI-ENDI 07A, could not be performed in time for this *Review*. Thus, the OUR FIT values quoted below use the previous OPAL results as in ABBI-ENDI.G 00.

$\Gamma(\ell^+ \nu)/\Gamma_{\text{total}}$ Γ_1/Γ ℓ indicates average over e, μ , and τ modes, not sum over modes.

39 ABAZOV

 10.61 ± 0.28

 39 ABAZOV 04D take into account all correlations to properly combine the CDF (ABE 95w) and DØ (ABBOTT 00B) measurements of the ratio R in the electron channel. The ratio R is defined as $[\sigma_W \cdot \text{B}(W \rightarrow e \nu_e)] \ / \ [\sigma_Z \cdot \text{B}(Z \rightarrow e e)]$. The combination gives $R^{Tevatron} = 10.59 \pm 0.23. \ \sigma_W \ / \ \sigma_Z$ is calculated at next–to–next–to–leading order (3.360 ± 0.051) . The branching fraction B($Z \rightarrow e e)$ is taken from this Review as $(3.363 \pm 0.004)\%$.

1.24 $^{+0.6}_{-0.4}$ 14 ARNISON 84D UA1 Repl. by ALBAJAR 89

 40 ABACHI 95D obtain this result from the measured $\sigma_W B(W \to \mu \nu) = 2.09 \pm 0.23 \pm 0.11$ nb and $\sigma_W B(W \to e \nu) = 2.36 \pm 0.07 \pm 0.13$ nb in which the first error is the combined statistical and systematic uncertainty, the second reflects the uncertainty in the luminosity.

41 ABE 921 obtain σ_W B($W \rightarrow \mu \nu$) = $2.21 \pm 0.07 \pm 0.21$ and combine with ABE 91c σ_W B($(W \rightarrow e \nu)$) to give a ratio of the couplings from which we derive this measurement.

 42 ABBOTT 00D measure $\sigma_{W}\times {\rm B}(W\to \tau\nu_{\tau})=2.22\pm0.09\pm0.10\pm0.10$ nb. Using the ABBOTT 00B result $\sigma_{W}\times {\rm B}(W\to e\nu_{e})=2.31\pm0.01\pm0.05\pm0.10$ nb, they quote the ratio of the couplings from which we derive this measurement.

quote the ratio of the couplings from which we derive this measurement. As ABE 92E use two procedures for selecting $W \to \tau \nu_{\tau}$ events. The missing E $_T$ trigger leads to $132\pm 14\pm 8$ events and the τ trigger to $47\pm 9\pm 4$ events. Proper statistical and systematic correlations are taken into account to arrive at σ B($W \to \tau \nu$) = 2.05 \pm 0.27 nb. Combined with ABE 91c result on σ B($W \to e \nu$), ABE 92E quote a ratio of the couplings from which we derive this measurement.

44 This measurement is derived by us from the ratio of the couplings of ALITTI 92F.

 $^{53} \text{ABBIENDI 06A measure} \ \langle N_{\text{charged}} \rangle = 38.74 \pm 0.12 \pm 0.26 \ \text{when both} \ W \ \text{bosons}$ decay hadronically and $\langle N_{\text{charged}} \rangle = 19.39 \pm 0.11 \pm 0.09 \ \text{when one} \ W \ \text{boson decays}$ semileptonically. The value quoted here is obtained under the assumption that there is no color reconnection between W bosons; the value is a weighted average taking into account correlations in the systematic uncertainties.

⁵⁴ ABREU,P 00F measure $\langle N_{\rm charged} \rangle = 39.12 \pm 0.33 \pm 0.36$ and $38.11 \pm 0.57 \pm 0.44$ in the fully hadronic final states at 189 and 183 GeV respectively, and $\langle N_{\rm charged} \rangle = 19.49 \pm 0.31 \pm 0.27$ and $19.78 \pm 0.49 \pm 0.43$ in the semileptonic final states. The value quoted is a weighted average without assuming any correlations.

quoted is a weighted average without assuming any correlations. ⁵⁵ ABBIENDI 99N use the final states $W^+W^- o q \overline{q} \ell \overline{\nu}_\ell$ to derive this value.

⁵⁶ ABREU 98c combine results from both the fully hadronic as well semileptonic W W final states after demonstrating that the W decay charged multiplicity is independent of the topology within errors.

TRIPLE GAUGE COUPLINGS (TGC'S)

Revised March 2012 by M.W. Grünewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

Fourteen independent couplings, 7 each for ZWW and γWW , completely describe the VWW vertices within the most general framework of the electroweak Standard Model (SM) consistent with Lorentz invariance and U(1) gauge invariance. Of each of the 7 TGC's, 3 conserve C and P individually, 3 violate CP, and one TGC violates C and P individually while conserving CP. Assumption of C and C conservation and electromagnetic gauge invariance reduces the independent C where C in the Standard Model at the tree level. The parameters C and C are related to the other three due to constraints

of gauge invariance as follows: $\kappa_Z = g_1^Z - (\kappa_\gamma - 1) \tan^2 \theta_W$ and $\lambda_Z = \lambda_\gamma$, where θ_W is the weak mixing angle. The W magnetic dipole moment, μ_W , and the W electric quadrupole moment, q_W , are expressed as $\mu_W = e \ (1 + \kappa_\gamma + \lambda_\gamma)/2M_W$ and $q_W = -e \ (\kappa_\gamma - \lambda_\gamma)/M_W^2$.

Precision measurements of suitable observables at LEP1 has already led to an exploration of much of the TGC parameter space. At LEP2, the VWW coupling arises in W-pair production via s-channel exchange, or in single W production via the radiation of a virtual photon off the incident e^+ or e^- . At the Tevatron and the LHC, hard-photon bremsstrahlung off a produced W or Z signals the presence of a triple-gauge vertex. In order to extract the value of one TGC, the others are generally kept fixed to their SM values.

While most analyses use the above gauge constraints in the extraction of TGCs, one analysis of W-pair events also determines the real and imaginary parts of all 14 couplings using unconstrained single-parameter fits [3]. The results are consistent.

⁵⁷ABDALLAH 10 use data on the final states $e^+e^- \rightarrow jj\ell\nu$, jjjj, jjX, ℓX , at center-of-mass energies between 189–209 GeV at LEP2, where j= jet, $\ell=$ lepton, and X represents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values.

at their SM values.

SSCHAEL 05A study single-photon, single-W, and WW-pair production from 183 to 209 GeV. The result quoted here is derived from the WW-pair production sample. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.

59 ABBIENDI 04D combine results from W^+W^- in all decay channels. Only CP-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $0.923 < g \frac{7}{1} < 1.054$.

60 ACHARD 04D study WW-pair production, single-W production and single-photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained from the WW-pair production sample including data from 161 to 183 GeV, ACCIA-RRI 990. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.

 61 ABAZOV 11 study the $p\overline{p}\to 3\ell\nu$ process arising in WZ production. They observe 34 WZ candidates with an estimated background of 6 events. An analysis of the p_T spectrum of the Z boson leads to a 95% C.L. limit of 0.944 $<~g_1^Z<1.154$, for a form factor $\Lambda=2$ TeV.

VALUE

- 62 AALTONEN 10K study $p\,\overline{p}\to W^+W^-$ with $W\to e/\mu\nu$. The p_T of the leading (second) lepton is required to be > 20 (10) GeV. The final number of events selected is 654 of which 320 \pm 47 are estimated to be background. The 95% C.L. interval is 0.76 $< g_1^Z < 1.34$ for $\Lambda = 1.5$ TeV and 0.78 $< g_1^Z < 1.30$ for $\Lambda = 2$ TeV.
- 63 ABAZOV 09AD study the $p\bar{p} \rightarrow \ell\nu$ 2jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is 0.88 $< g_1^Z < 1.20$.
- 64 ABAZOV 09AJ study the $p\overline{p} \to 2\ell 2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of 0.86 $<~g_1^{\,Z}~<$ 1.3, for a form

65 1 ABDALLAH 08c determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (q\,q)(\ell\nu)$, where $\ell=e$ or μ . Values of all other couplings are fixed to their standard model values.

- 66 ABAZOV 072 set limits on anomalous TGCs using the measured cross section and $p_T(Z)$ distribution in WZ production with both the W and the Z decaying leptonically into electrons and muons. Setting the other couplings to their standard model values, the 95% C.L. limit for a form factor scale $\Lambda=2$ TeV is 0.86 $< g_1^Z < 1.35$.
- ⁶⁷ABAZOV 05s study $\overline{p}p \rightarrow WZ$ production with a subsequent trilepton decay to $\ell\nu\ell'\overline{\ell'}$ $(\ell \text{ and } \ell' = e \text{ or } \mu)$. Three events (estimated background 0.71 \pm 0.08 events) with WZdecay characteristics are observed from which they derive limits on the anomalous WWZcouplings. The 95% CL limit for a form factor scale $\Lambda=1.5~{
 m TeV}$ is 0.51 $< g_1^Z <$ 1.66, fixing λ_Z and κ_Z to their Standard Model values.
- 68 ABREU 011 combine results from e^+e^- interactions at 189 GeV leading to W^+W^- and $We\,\nu_e$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is 0.84 $< g_1^Z < 1.13$.
- ⁶⁹ ABBOTT 991 perform a simultaneous fit to the $W\gamma$, $WW\to dilepton$, $WW/WZ\to e\nu jj$, $WW/WZ\to \mu\nu jj$, and $WZ\to trilepton$ data samples. For $\Lambda=2.0$ TeV, the 95%CL limits are $0.63< g_1^Z<1.57$, fixing λ_Z and κ_Z to their Standard Model values, and assuming Standard Model values for the $WW\gamma$ couplings.

OUR FIT below is obtained by combining the measurements taking into account properly the common systematic errors (see LEPEWWG/TGC/2005-01 at http://lepewwg.web.cern.ch/LEPEWWG/lepww/tgc).

- 70 ABDALLAH 10 use data on the final states $e^+e^- o jj\ell\nu$, jjjj, jjX, ℓX , at center-of-mass energies between 189–209 GeV at LEP2, where j= jet, $\ell=$ lepton, and Xrepresents missing momentum. The fit is carried out keeping all other parameters fixed at their SM values
- 71 SCHAEL 05A study single-photon, single-W, and WW-pair production from 183 to 209 GeV. Each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values.
- 72 ABBIENDI 04D combine results from W^+W^- in all decay channels. Only CP-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $0.73 < \kappa_{\gamma} < 1.07$.
- 73 ACHARD 04D study WW-pair production, single—W production and single—photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained including data from 161 to 183 GeV, ACCIARRI 990. Each parameter is determined. from a single-parameter fit in which the other parameters assume their Standard Model
- 74 ABAZOV 11AC study $W\gamma$ production in $p\overline{p}$ collisions at 1.96 TeV, with the W decay products containing an electron or a muon. They select 196 (363) events in the electron (muon) mode, with a SM expectation of 190 (372) events. A likelihood fit to the photon E_T spectrum above 15 GeV yields at 95% C.L. the result: $0.6 < \kappa_\gamma < 1.4$ for a form factor $\Lambda = 2$ TeV.

- 75 CHATRCHYAN 11M study $W\gamma$ production in pp collisions at $\sqrt{s}=7$ TeV using 36 pb $^{-1}$ pp data with the W decaying to electron and muon. The total cross section is measured for photon transverse energy $E_T^{\gamma}>10~{
 m GeV}$ and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell,\gamma)>0.7$. The number of candidate (background) events is 452 (228 \pm 21) for the electron channel and 520 (277 \pm 25) for the muon channel. Setting other couplings to their standard model value, they derive a 95% CL limit of $-0.11<\kappa_{\gamma}<2.04$.
- 76 AALTONEN 10K study $p\overline{p}\to W^+W^-$ with $W\to e/\mu\nu$. The p_T of the leading (second) lepton is required to be >20 (10) GeV. The final number of events selected is 654 of which 320 ± 47 are estimated to be background. The 95% C.L. interval is $0.37 < \kappa_\gamma < 1.72$ for $\Lambda=1.5$ TeV and $0.43 < \kappa_\gamma < 1.65$ for $\Lambda=2$ TeV.
- 77 AARON 09B study single-W production in ep collisions at 0.3 TeV C.M. energy. They select 53 $W\to e/\mu$ events with a standard model expectation of 54.1 \pm 7.4 events. Fitting the transverse momentum spectrum of the hadronic recoil system they obtain a 95% C.L. limit of $-3.7 < \kappa_{\gamma} < -1.5$ or $0.3 < \kappa_{\gamma} < 1.5$, where the ambiguity is due to the quadratic dependence of the cross section to the coupling parameter.
- ⁷⁸ABAZOV 09AD study the $p\overline{p} \rightarrow \ell \nu$ 2jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $0.56 < \kappa_\gamma < 1.55$.
- 79 ABAZOV 09AJ study the $\rho\overline{p} \to 2\ell 2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of 0.46 $< \kappa_{\gamma} < 1.83$, for a form factor $\Lambda = 2 \text{ TeV}$.
- factor $\Lambda=2$ TeV. 80 ABAZOV 08R use 0.7 fb $^{-1}$ $p\bar{p}$ data at $\sqrt{s}=1.96$ TeV to select 263 $W\gamma+X$ events, of which 187 constitute signal, with the W decaying into an electron or a muon, which is required to be well separated from a photon with $E_T>9$ GeV. A likelihood fit to the photon E_T spectrum yields a 95% CL limit $0.49<\kappa_{\gamma}<1.51$ with other couplings fixed to their Standard Model values.
- 81 ABDALLAH 08c determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (q\,q)(\ell\nu)$, where $\ell=e$ or μ . Values of all other couplings are fixed to their standard model values.
- 82 AALTONEN 07L set limits on anomalous TGCs using the $p_T(W)$ distribution in WWand WZ production with the W decaying to an electron or muon and the Z to 2 jets. Setting other couplings to their standard model value, the 95% C.L. limits are 0.54 < 1.39 for a form factor scale $\Lambda = 1.5$ TeV.
- 83 ABAZOV 06H study $\overline{p}p \rightarrow WW$ production with a subsequent decay $WW \rightarrow$ $e^{+\nu_e}e^{-\overline{\nu_e}}, WW \rightarrow e^{+\nu_\mu}\mu^{-\overline{\nu}\mu} \text{ or } WW \rightarrow \mu^+\nu_\mu\mu^-\overline{\nu}\mu. \text{ The 95\% C.L. limit for a form factor scale } \Lambda=1 \text{ TeV is }-0.05 < \kappa_\gamma < 2.29, \text{ fixing } \lambda_\gamma = 0. \text{ With the assumption } \lambda_\gamma =$ that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit (Λ = 2 TeV) is $0.68 < \kappa < 1.45$.
- ⁸⁴ ABAZOV 05J perform a likelihood fit to the photon \emph{E}_T spectrum of $\emph{W}\gamma$ + X events, where the W decays to an electron or muon which is required to be well separated from the photon. For $\Lambda=2.0$ TeV the 95% CL limits are 0.12 $<\kappa_{\gamma}<1.96$. In the fit λ_{γ} is kept fixed to its Standard Model value.
- 85 ABREU 01I combine results from e^+e^- interactions at 189 GeV leading to $W^+W^-,$ $Wev_e,$ and $\nu\overline{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $0.87<\kappa_{\gamma}<1.68.$
- 86 BREITWEG 00 search for W production in events with large hadronic p_T . For $p_T>$ 20 GeV, the upper limit on the cross section gives the 95%CL limit 3.7 $<\kappa_{\gamma}<$ 2.5 (for
- 87 $_{
 m ABBOTT}$ 991 perform a simultaneous fit to the $W\gamma$, WW
 ightharpoonup dilepton, WW/WZ
 ightharpoonup e
 ujj, $WW/WZ
 ightharpoonup \mu
 ujj$, and WZ
 ightharpoonup trilepton data samples. For $\Lambda = 2.0$ TeV, the 95%CL limits are $0.75 < \kappa_{\gamma} < 1.39$.

OUR FIT below is obtained by combining the measurements taking into account properly the common systematic errors (see LEPEWWG/TGC/2005-01 at http://lepewwg.web.cern.ch/LEPEWWG/lepww/tgc).

W

- 88 ABDALLAH 10 use data on the final states $e^+e^-\to jj\ell\nu,jjjj,jjX,\ell X$, at center-of-mass energies between 189–209 GeV at LEP2, where j= jet, $\ell=$ lepton, and X represents missing momentum. The fit is carried out keeping all other parameters fixed
- at their SM values.

 89 SCHAEL 05A study single-photon, single-W, and WW-pair production from 183 to 209 GeV. Each parameter is determined from a single-parameter fit in which the other
- parameters assume their Standard Model values. 90 ABBIENDI 04D combine results from W^+W^- in all decay channels. Only CP-conserving couplings are considered and each parameter is determined from a single-parameter fit in which the other parameters assume their Standard Model values. The 95% confidence interval is $-0.13 < \lambda_{\gamma} < 0.01$.
- 91 ACHARD 04D study $\stackrel{7}{WW}$ —pair production, single—W production and single—photon production with missing energy from 189 to 209 GeV. The result quoted here is obtained including data from 161 to 183 GeV, ACCIARRI 99Q. Each parameter is determined from a single—parameter fit in which the other parameters assume their Standard Model
- 92 ABAZOV 11AC study $W\gamma$ production in $p\overline{p}$ collisions at 1.96 TeV, with the W decay products containing an electron or a muon. They select 196 (363) events in the electron (muon) mode, with a SM expectation of 190 (372) events. A likelihood fit to the photon E_T spectrum above 15 GeV yields at 95% C.L. the result: - 0.08 $< \, \lambda_{\gamma} \, <$ 0.07 for a formfactor $\Lambda = 2 \text{ TeV}$
- 93 CHATRCHYAN 11M study $W\gamma$ production in pp collisions at $\sqrt{s}=$ 7 TeV using 36 pb $^{-1}$ pp data with the W decaying to electron and muon. The total cross section is measured for photon transverse energy $E_T^\gamma>10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell,\gamma)>0.7$. The number of candidate (background) events is 452 (228 \pm 21) for the electron channel and 520 (277 \pm 25) for the muon channel. Setting other couplings to their standard model value, the property of the control of the couplings of the couplings of the couplings to the couplings of the coupling of the couplings of the coupling of th they derive a 95% CL limit of $-0.18 < \lambda_{\gamma} < 0.17$.
- 94 AARON 09B study single-W production in $e\,p$ collisions at 0.3 TeV C.M. energy. They select 53 $W o e/\mu$ events with a standard model expectation of 54.1 \pm 7.4 events. Fitting the transverse momentum spectrum of the hadronic recoil system they obtain a 95% C.L. limit of $-2.5 < \lambda_{\gamma} < 2.5$
- 95 ABAZOV 09AD study the $p\overline{p} \rightarrow \ell \nu$ 2jet process arising in WW and WZ production. They select 12,473 (14,392) events in the electron (muon) channel with an expected di-boson signal of 436 (527) events. The results on the anomalous couplings are derived from an analysis of the p_T^{\prime} spectrum of the 2-jet system and quoted at 68% C.L. and for a form factor of 2 TeV. This measurement is not used for obtaining the mean as it is for a specific form factor. The 95% confidence interval is $-0.10 < \stackrel{\circ}{\lambda_{\gamma}} < 0.11$
- 96 ABAZOV 09AJ study the $p\overline{p} \to 2\ell 2\nu$ process arising in WW production. They select 100 events with an expected WW signal of 65 events. An analysis of the p_T spectrum of the two charged leptons leads to 95% C.L. limits of $-0.14 < \lambda_{\gamma} < 0.18$, for a form factor $\Lambda = 2$ TeV.
- 97 actor $\Lambda=2$ TeV. 97 ABAZOV 08R use 0.7 fb $^{-1}$ $p\,\overline{p}$ data at $\sqrt{s}=1.96$ TeV to select 263 $W\gamma+X$ events, of which 187 constitute signal, with the W decaying into an electron or a muon, which is required to be well separated from a photon with $E_T>9$ GeV. A likelihood fit to the photon E_T spectrum yields a 95% CL limit $-0.12 < \lambda_{\gamma} < 0.13$ with other couplings fixed to their Standard Model values.
- 98 ABDALLAH 08c determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (q\,q)(\ell\nu)$, where $\ell=e$ or μ . Values of all other couplings are fixed to their standard model values.
- of all other couplings are nixed to their standard model values. $P_T(W) \ \text{distribution in } WW \ \text{and } WZ \ \text{production} \ \text{with the } W \ \text{decaying to an electron or muon and the } Z \ \text{to 2} \ \text{jets.} \ \text{Setting other couplings to their standard model value, the 95% C.L. limits are } -0.18 < \lambda_{\gamma} < 0.17 \ \text{for a form factor scale } \Lambda = 1.5 \ \text{TeV}.$
- 100 ABAZOV 06H study $\overline{p}p \rightarrow WW$ production with a subsequent decay $WW \rightarrow$ $e^+\nu_e e^-\overline{\nu}_e, \ WW \rightarrow e^+\nu_e \mu^+\nu_\mu \ \text{or} \ WW \rightarrow \mu^+\nu_\mu \mu^-\overline{\nu}_\mu \ \text{The 95\% C.L. limit for a form factor scale } \Lambda = 1 \ \text{TeV} \ \text{is} -0.97 < \lambda_\gamma < 1.04, \ \text{fixing } \kappa_\gamma = 1. \ \text{With the assumption}$ that the $WW\gamma$ and WWZ couplings are equal the 95% C.L. one-dimensional limit (Λ 2 TeV) is $-0.29 < \lambda < 0.30$.
- 101 ABAZOV 05J perform a likelihood fit to the photon $\it E_{T}$ spectrum of $\it W\gamma + X$ events, where the W decays to an electron or muon which is required to be well separated from the photon. For $\Lambda=2.0$ TeV the 95% CL limits are $-0.20 < \lambda_{\gamma} < 0.20$. In the fit κ_{γ} is kept fixed to its Standard Model value.
- 102 7 ABREU 011 combine results from e $^{+}$ e $^{-}$ interactions at 189 GeV leading to W^{+} W^{-} , $We\nu_{e}$, and $\nu\overline{\nu}\gamma$ final states with results from ABREU 99L at 183 GeV. The 95% confidence interval is $-0.11 < \lambda_{\gamma} < 0.23$.
- $^{'}$ BREITWEG 00 search for W production in events with large hadronic p_T . For $p_T>$ 20 GeV, the upper limit on the cross section gives the 95%CL limit $-3.2<\lambda_{\gamma}<3.2$ for κ_{γ} fixed to its Standard Model value.
- $^{\Lambda}$ BBOTT 99I perform a simultaneous fit to the $W\gamma,WW\to$ dilepton, $WW/WZ\to e\nu jj,\,WW/WZ\to \mu\nu jj$, and $WZ\to$ trilepton data samples. For $\Lambda=2.0$ TeV, the 95%CL limits are $-0.18<\lambda_{\gamma}<0.19$.

This coupling is $\it CP$ -conserving ($\it C$ - and $\it P$ - separately conserving). EVTS DO CUMENT ID

- $^{124}\mathsf{ABDALLAH}$ 08C determine this triple gauge coupling from the measurement of the spin density matrix elements in $e^+e^- \to W^+W^- \to (q\,q)(\ell\nu)$, where $\ell=e$ or μ . Values of all other couplings are fixed to their standard model values.
- 125 ABBIENDI 01H study W-pair events, with one leptonically and one hadronically decaying $\it W$. The coupling is extracted using information from the $\it W$ production angle together with decay angles from the leptonically decaying $\it W$.
- 126 BLINOV 11 use the LEP-average $e^+\,e^ \rightarrow$ $W^+\,W^-$ cross section data for $\sqrt{s}=$ 183–207 GeV to determine an upper limit on the TGC $\widetilde{\lambda}_Z$. The average values of the cross sections as well as their correlation matrix, and standard model expectations of the cross sections are taken from the LEPEWWG note hep-ex/0612034. At 95% confidence level $|\tilde{\lambda}_Z| < 0.31$

W ANOMALOUS MAGNETIC MOMENT

The full magnetic moment is given by $\mu_W=e(1+\kappa+\lambda)/2m_W$. In the Standard Model, at tree level, $\kappa=1$ and $\lambda=0$. Some papers have defined $\Delta \kappa = 1 - \kappa$ and assume that $\lambda = 0$. Note that the electric quadrupole moment is given by $-e(\kappa - \lambda)/m_W^2$. A description of the parameterization of these moments and additional references can be found in HAGIWARA 87 and BAUR 88. The parameter Λ appearing in the theoretical limits below is a regularization cutoff which roughly corresponds to the energy scale where the structure of the W boson becomes manifest.

- 127 ABREU 011 combine results from $e^+\,e^-$ interactions at 189 GeV leading to $W^+\,W^-$, $We
 u_e$, and $u\overline{
 u}\gamma$ final states with results from ABREU 99L at 183 GeV to determine Δg_1^Z , $\Delta \kappa_\gamma$, and λ_γ . $\Delta \kappa_\gamma$ and λ_γ are simultaneously floated in the fit to determine
- 128 ABE 95G report $-1.3 < \kappa < 3.2$ for $\lambda = 0$ and $-0.7 < \lambda < 0.7$ for $\kappa = 1$ in $\rho \overline{\rho} \rightarrow \ e \ \nu_e \gamma X$ and $\mu \nu_{\mu} \gamma X$ at $\sqrt{s} = 1.8$ TeV.
- 129 ALITTI 92c measure $\kappa=1^{+2.6}_{-2.2}$ and $\lambda=0^{+1.7}_{-1.8}$ in $p\overline{p}\rightarrow e\,\nu\gamma+$ X at $\sqrt{s}=630$ GeV. At 95%CL they report $-3.5<\kappa<5.9$ and $-3.6<\lambda<3.5$.
- 130 SAMUEL 192 use preliminary CDF and UA2 data and find $-2.4 < \kappa < 3.7$ at 96%CL and $-3.1 < \kappa < 4.2$ at 95%CL respectively. They use data for $W\gamma$ production and radiative W decay.
- 131 SAMUEL 91 use preliminary CDF data for $p\overline{p} o W\gamma$ X to obtain $-11.3 \le \Delta \kappa \le$ 10.9. Note that their $\kappa = 1 - \Delta \kappa$.
- 132 GRIFOLS 88 uses deviation from ho parameter to set limit $\Delta\kappa \lesssim$ 65 (M_W^2/Λ^2) .
- 133 GROTCH 87 finds the limit $-37 < \Delta \kappa < 73.5 \ (90\% \ \text{CL})$ from the experimental limits on $e^+\,e^-\to \nu\overline{\nu}\gamma$ assuming three neutrino generations and $-19.5<\Delta\kappa<$ 56 for four generations. Note their $\Delta\kappa$ has the opposite sign as our definition.

- 134 VA NDERBIJ 87 uses existing limits to the photon structure to obtain $|\Delta\kappa|$ (m_W/Λ) . In addition VANDERBIJ 87 discusses problems with using the ρ parameter of the Standard–Model to determine $\Delta\kappa$.
- 135 GRAU 85 uses the muon anomaly to derive a coupled limit on the anomalous magnetic dipole and electric quadrupole (λ) moments $1.05>\Delta\kappa\ln(\Lambda/m_W)+\lambda/2>-2.77$. In he Standard Model $\lambda=0$.
- $136\,\mathrm{SUZUKl}$ 85 uses partial-wave unitarity at high energies to obtain $|\Delta\kappa|\lesssim190$ $(m_W/\Lambda)^2$. From the anomalous magnetic moment of the muon, SUZUKI 85 obtains $|\Delta\kappa|\lesssim 2.2/{\ln(\Lambda/m_W)}$. Finally SUZUKI 85 uses deviations from the ho parameter and obtains a very qualitative, order-of-magnitude limit $|\Delta\kappa|\lesssim 150~(m_W/\Lambda)^4$ if $|\Delta\kappa|\ll 100$
- 137 HERZOG 84 consider the contribution of W-boson to muon magnetic moment including anomalous coupling of $WW\gamma$. Obtain a limit $-1 < \Delta\kappa < 3$ for $\Lambda \gtrsim 1$ TeV.

ANOMALOUS W/Z QUARTIC COUPLINGS

Revised March 2012 by M.W. Grünewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

The Standard Model quartic couplings, WWWW, WWZZ, $WWZ\gamma$, $WW\gamma\gamma$, and $ZZ\gamma\gamma$ lead to negligible effects at LEP energies, while they are important at a TeV Linear Collider. Outside the Standard Model framework, possible quartic couplings, a_0, a_c, a_n , are expressed in terms of the following dimension-6 operators [1,2];

$$\begin{split} L_6^0 &= -\frac{e^2}{16\Lambda^2} \; a_0 \; F^{\mu\nu} \; F_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}_\alpha \\ L_6^c &= -\frac{e^2}{16\Lambda^2} \; a_c \; F^{\mu\alpha} \; F_{\mu\beta} \vec{W}^\beta \cdot \vec{W}_\alpha \\ L_6^n &= -i \frac{e^2}{16\Lambda^2} \; a_n \epsilon_{ijk} \; W^{(i)}_{\mu\alpha} \; W^{(j)}_\nu \; W^{(k)\alpha} F^{\mu\nu} \\ \widetilde{L}_6^0 &= -\frac{e^2}{16\Lambda^2} \; \widetilde{a}_0 \; F^{\mu\nu} \; \widetilde{F}_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}_\alpha \\ \widetilde{L}_6^n &= -i \frac{e^2}{16\Lambda^2} \; \widetilde{a}_n \epsilon_{ijk} \; W^{(i)}_{\mu\alpha} \; W^{(j)}_\nu \; W^{(k)\alpha} \widetilde{F}^{\mu\nu} \end{split}$$

where F, W are photon and W fields, L_6^0 and L_6^c conserve C, P separately $(L_6^0$ conserves only C) and generate anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ couplings, L_6^n violates CP (\widetilde{L}_6^n violates both C and P) and generates an anomalous $W^+W^-Z\gamma$ coupling, and Λ is an energy scale for new physics. For the $ZZ\gamma\gamma$ coupling the CP-violating term represented by L_6^n does not contribute. These couplings are assumed to be real and to vanish at tree level in the Standard Model.

Within the same framework as above, a more recent description of the quartic couplings [3] treats the anomalous parts of the $WW\gamma\gamma$ and $ZZ\gamma\gamma$ couplings separately leading to two sets parameterized as a_0^V/Λ^2 and a_c^V/Λ^2 , where V=W or Z.

At LEP the processes studied in search of these quartic couplings are $e^+e^- \to WW\gamma$, $e^+e^- \to \gamma\gamma\nu\overline{\nu}$, and $e^+e^- \to$ $Z\gamma\gamma$ and limits are set on the quantities a_0^W/Λ^2 , a_c^W/Λ^2 , a_n/Λ^2 . The characteristics of the first process depend on all the three couplings whereas those of the latter two depend only on the two CP-conserving couplings. The sensitive measured variables are the cross sections for these processes as well as the energy and angular distributions of the photon and recoil mass to the photon pair.

 $138\,\mathrm{ABBIENDI}$ 04B select 187 $e^+\,e^-\to W^+\,W^-\gamma$ events in the C.M. energy range 180–209 GeV, where $E_\gamma>2.5$ GeV, the photon has a polar angle $\left|\cos\theta_\gamma\right|<0.975$ and is well isolated from the nearest jet and charged lepton, and the effective masses of both fermion-antifermion systems agree with the W mass within 3 Γ_W . The measured differential cross section as a function of the photon energy and photon polar angle is used to extract the 95% CL limits: $-0.020\,\,\mathrm{GeV}^{-2} < a_0/\Lambda^2 < 0.020\,\,\mathrm{GeV}^{-2}, -0.053\,\,\mathrm{GeV}^{-2} < a_c/\Lambda^2 < 0.037\,\,\mathrm{GeV}^{-2}$ and $-0.16\,\,\mathrm{GeV}^{-2} < a_n/\Lambda^2 < 0.15\,\,\mathrm{GeV}^{-2}$.

139 ABBIENDI 04L select 20 $e^+e^- \to \nu\overline{\nu}\gamma\gamma$ acoplanar events in the energy range 180–209 GeV and 176 $e^+e^- \to q\,\overline{q}\gamma\gamma$ events in the energy range 130–209 GeV. These samples are used to constrain possible anomalous $W^+W^-\gamma\gamma$ and $Z\,Z\gamma\gamma$ quartic couplings. Further combining with the $W^+W^-\gamma\gamma$ sample of ABBIENDI 04B the following one-parameter 95% CL limits are obtained: -0.007 $< a_d^Z/\Lambda^2 < 0.023~{\rm GeV}^{-2}, -0.029 < a_d^Z/\Lambda^2 < 0.029~{\rm GeV}^{-2}, -0.052 < a_c^W/\Lambda^2 < 0.037~{\rm GeV}^{-2}.$

140 In the CM energy range 183 to 209 GeV HEISTER 04A select 30 $e^+\,e^- \to \nu \overline{\nu} \gamma \gamma$ events with two acoplanar, high energy and high transverse momentum photons. The photon-photon acoplanarity is required to be > 5°, $E_\gamma/\sqrt{s}>0.025$ (the more energetic photon having energy > 0.2 \sqrt{s}), $p_{T_\gamma}/E_{\rm beam}>0.05$ and $|\cos\theta_\gamma|<0.94$. A likelihood fit to the photon energy and recoil missing mass yields the following one-parameter 95% CL limits: $-0.012 < a_0^Z/\Lambda^2 < 0.019~{\rm GeV}^{-2}, -0.041 < a_C^Z/\Lambda^2 < 0.044~{\rm GeV}^{-2}, -0.060 < a_0^W/\Lambda^2 < 0.055~{\rm GeV}^{-2}, -0.099 < a_C^W/\Lambda^2 < 0.093~{\rm GeV}^{-2}.$

141 ABDALLAH 031 select 122 $e^+e^- \to W^+W^-\gamma$ events in the C.M. energy range 189–209 GeV, where $E_{\gamma} >$ 5 GeV, the photon has a polar angle $|\cos\theta_{\gamma}| < 0.95$ and is well isolated from the nearest charged fermion. A fit to the photon energy spectra yields $a_{c}/\Lambda^{2} = 0.000^{+}_{-0.010}^{+0.019} \text{ GeV}^{-2}$, $a_{0}/\Lambda^{2} = -0.004^{+0.018}_{-0.010} \text{ GeV}^{-2}$, $\bar{a}_{0}/\Lambda^{2} = -0.007^{+0.019}_{-0.010} \text{ GeV}^{-2}$, $a_{0}/\Lambda^{2} = -0.09^{+0.16}_{-0.05} \text{ GeV}^{-2}$, and $\bar{a}_{0}/\Lambda^{2} = +0.05^{+0.07}_{-0.15} \text{ GeV}^{-2}$, keeping the other parameters fixed to their Standard Model values (0). The 95% CL limits are: $-0.063 \text{ GeV}^{-2} < a_{c}/\Lambda^{2} < +0.032 \text{ GeV}^{-2}$, $-0.020 \text{ GeV}^{-2} < a_{0}/\Lambda^{2} < +0.020 \text{ GeV}^{-2}$, $-0.020 \text{ GeV}^{-2} < \bar{a}_{0}/\Lambda^{2} < +0.020 \text{ GeV}^{-2}$, $-0.18 \text{ GeV}^{-2} < a_{n}/\Lambda^{2} < +0.14 \text{ GeV}^{-2}$, $-0.16 \text{ GeV}^{-2} < \bar{a}_{n}/\Lambda^{2} < +0.17 \text{ GeV}^{-2}$.

142 ACHARD 02F select 86 $e^+e^- \to W^+W^-\gamma$ events at 192–207 GeV, where $E_\gamma > 5$ GeV and the photon is well isolated. They also select 43 acoplanar $e^+e^- \to \nu \overline{\nu} \gamma \gamma$ events in this energy range, where the photon energies are >5 GeV and >1 GeV and the photon polar angles are between 14° and 166°. All these 43 events are in the recoil mass region corresponding to the Z (75–110 GeV). Using the shape and normalization of the photon spectra in the $W^+W^-\gamma$ events, and combining with the 42 event sample from 189 GeV data (ACCIARRI 00T), they obtain: $a_0/\Lambda^2 = 0.000 \pm 0.010$ GeV $^{-2}$, $a_c/\Lambda^2 = -0.013 \pm 0.023$ GeV $^{-2}$, and $a_n/\Lambda^2 = -0.002 \pm 0.076$ GeV $^{-2}$. Further combining the analyses of $W^+W^-\gamma$ events with the low recoil mass region of $\nu \overline{\nu} \gamma \gamma$ events (including samples collected at 183 +189 GeV), they obtain the following one-parameter 95% CL limits: -0.015 GeV $^{-2}$ </br> $= -0.013 \pm 0.023$ GeV $^{-2}$ </br> = -0.013 GeV $^{-2}$ </br> = -0.013 GeV $^{-2}$ </br> = -0.013 GeV $^{-2}$ </br> = -0.014 GeV $^{-2}$ </br> = -0.015 GeV $^{-2}$ </br> = -0.015 GeV $^{-2}$ </br> = -0.014 GeV $^{-2}$ </br> = -0.014 GeV $^{-2}$ </br> = -0.015 GeV $^{-2}$ </br> = -0.014 GeV $^{-2}$ </br>

THE Z BOSON

Revised March 2009 by M. Grünewald (U. College Dublin and U. Ghent), and A. Gurtu (Tata Inst.).

Precision measurements at the Z-boson resonance using electron–positron colliding beams began in 1989 at the SLC and at LEP. During 1989–95, the four LEP experiments (ALEPH, DELPHI, L3, OPAL) made high-statistics studies of the production and decay properties of the Z. Although the SLD experiment at the SLC collected much lower statistics, it was able to match the precision of LEP experiments in determining

the effective electroweak mixing angle $\sin^2 \overline{\theta}_W$ and the rates of Z decay to b- and c-quarks, owing to availability of polarized electron beams, small beam size, and stable beam spot.

The Z-boson properties reported in this section may broadly be categorized as:

- The standard 'lineshape' parameters of the Z consisting of its mass, M_Z , its total width, Γ_Z , and its partial decay widths, $\Gamma(\text{hadrons})$, and $\Gamma(\ell \overline{\ell})$ where $\ell = e, \mu, \tau, \nu$;
- Z asymmetries in leptonic decays and extraction of Z couplings to charged and neutral leptons;
- The b- and c-quark-related partial widths and charge asymmetries which require special techniques;
- Determination of Z decay modes and the search for modes that violate known conservation laws;
- \bullet Average particle multiplicities in hadronic Z decay;
- Z anomalous couplings.

The effective vector and axial-vector coupling constants describing the Z-to-fermion coupling are also measured in $p\bar{p}$ and ep collisions at the Tevatron and at HERA. The corresponding cross-section formulae are given in Section 39 (Cross-section formulae for specific processes) and Section 16 (Structure Functions) in this Review. In this minireview, we concentrate on the measurements in e^+e^- collisions at LEP and SLC.

The standard 'lineshape' parameters of the Z are determined from an analysis of the production cross sections of these final states in e^+e^- collisions. The $Z\to \nu\overline{\nu}(\gamma)$ state is identified directly by detecting single photon production and indirectly by subtracting the visible partial widths from the total width. Inclusion in this analysis of the forward-backward asymmetry of charged leptons, $A_{FB}^{(0,\ell)}$, of the τ polarization, $P(\tau)$, and its forward-backward asymmetry, $P(\tau)^{fb}$, enables the separate determination of the effective vector (\overline{g}_V) and axial vector (\overline{g}_A) couplings of the Z to these leptons and the ratio $(\overline{g}_V/\overline{g}_A)$, which is related to the effective electroweak mixing angle $\sin^2 \overline{\theta}_W$ (see the "Electroweak Model and Constraints on New Physics" review).

Determination of the b- and c-quark-related partial widths and charge asymmetries involves tagging the b and c quarks for which various methods are employed: requiring the presence of a high momentum prompt lepton in the event with high transverse momentum with respect to the accompanying jet; impact parameter and lifetime tagging using precision vertex measurement with high-resolution detectors; application of neural-network techniques to classify events as b or non-b on a statistical basis using event—shape variables; and using the presence of a charmed meson (D/D^*) or a kaon as a tag.

Z-parameter determination

LEP was run at energy points on and around the Z mass (88–94 GeV) constituting an energy 'scan.' The shape of the cross-section variation around the Z peak can be described by a Breit-Wigner ansatz with an energy-dependent

total width [1–3]. The **three** main properties of this distribution, viz., the **position** of the peak, the **width** of the distribution, and the **height** of the peak, determine respectively the values of M_Z , Γ_Z , and $\Gamma(e^+e^-) \times \Gamma(f\overline{f})$, where $\Gamma(e^+e^-)$ and $\Gamma(f\overline{f})$ are the electron and fermion partial widths of the Z. The quantitative determination of these parameters is done by writing analytic expressions for these cross sections in terms of the parameters, and fitting the calculated cross sections to the measured ones by varying these parameters, taking properly into account all the errors. Single-photon exchange (σ_{γ}^0) and γ -Z interference $(\sigma_{\gamma Z}^0)$ are included, and the large $(\sim 25~\%)$ initial-state radiation (ISR) effects are taken into account by convoluting the analytic expressions over a 'Radiator Function' [1–5] H(s,s'). Thus for the process $e^+e^- \to f\overline{f}$:

$$\sigma_f(s) = \int H(s, s') \ \sigma_f^0(s') \ ds' \tag{1}$$

$$\sigma_f^0(s) = \sigma_Z^0 + \sigma_\gamma^0 + \sigma_{\gamma Z}^0 \tag{2}$$

$$\sigma_{Z}^{0} = \frac{12\pi}{M_{Z}^{2}} \ \frac{\Gamma(e^{+}e^{-})\Gamma(f\overline{f})}{\Gamma_{Z}^{2}} \ \frac{s \ \Gamma_{Z}^{2}}{(s-M_{Z}^{2})^{2} \ + \ s^{2}\Gamma_{Z}^{2}/M_{Z}^{2}} \ (3)$$

$$\sigma_{\gamma}^0 = \frac{4\pi\alpha^2(s)}{3s} \ Q_f^2 N_c^f \tag{4}$$

$$\sigma_{\gamma Z}^0 = -\; \frac{2\sqrt{2}\alpha(s)}{3} \;\; (Q_f G_F N_c^f \mathcal{G}_V^e \mathcal{G}_V^f)$$

$$\times \frac{(s - M_Z^2)M_Z^2}{(s - M_Z^2)^2 + s^2\Gamma_Z^2/M_Z^2} \tag{5}$$

where Q_f is the charge of the fermion, $N_c^f = 3$ for quarks and 1 for leptons, and \mathcal{G}_V^f is the vector coupling of the Z to the fermion-antifermion pair $f\bar{f}$.

Since $\sigma_{\gamma Z}^0$ is expected to be much less than σ_Z^0 , the LEP Collaborations have generally calculated the interference term in the framework of the Standard Model. This fixing of $\sigma_{\gamma Z}^0$ leads to a tighter constraint on M_Z , and consequently a smaller error on its fitted value. It is possible to relax this constraint and carry out the fit within the S-matrix framework, which is briefly described in the next section.

In the above framework, the QED radiative corrections have been explicitly taken into account by convoluting over the ISR and allowing the electromagnetic coupling constant to run [6]: $\alpha(s) = \alpha/(1 - \Delta \alpha)$. On the other hand, weak radiative corrections that depend upon the assumptions of the electroweak theory and on the values of M_{top} and M_{Higgs} are accounted for by absorbing them into the couplings, which are then called the effective couplings \mathcal{G}_V and \mathcal{G}_A (or alternatively the effective parameters of the \star scheme of Kennedy and Lynn [7].)

 \mathcal{G}_A^V and \mathcal{G}_A^f are complex numbers with small imaginary parts. As experimental data does not allow simultaneous extraction of both real and imaginary parts of the effective couplings, the convention $g_A^f = \operatorname{Re}(\mathcal{G}_A^f)$ and $g_V^f = \operatorname{Re}(\mathcal{G}_V^f)$ is used and the imaginary parts are added in the fitting code [4].

Defining

$$A_f = 2 \frac{g_V^f \cdot g_A^f}{(g_V^f)^2 + (g_A^f)^2} \tag{6}$$

Z

the lowest-order expressions for the various lepton-related asymmetries on the Z pole are [8–10] $A_{FB}^{(0,\ell)}=(3/4)A_eA_f$, $P(\tau)=-A_\tau$, $P(\tau)^{fb}=-(3/4)A_e$, $A_{LR}=A_e$. The full analysis takes into account the energy-dependence of the asymmetries. Experimentally A_{LR} is defined as $(\sigma_L-\sigma_R)/(\sigma_L+\sigma_R)$, where $\sigma_{L(R)}$ are the $e^+e^-\to Z$ production cross sections with left- (right)-handed electrons.

The definition of the partial decay width of the Z to $f\overline{f}$ includes the effects of QED and QCD final-state corrections, as well as the contribution due to the imaginary parts of the couplings:

$$\Gamma(f\overline{f}) = \frac{G_F M_Z^3}{6\sqrt{2}\pi} N_c^f (\left| \mathcal{G}_A^f \right|^2 R_A^f + \left| \mathcal{G}_V^f \right|^2 R_V^f) + \Delta_{ew/QCD} \quad (7)$$

where R_V^f and R_A^f are radiator factors to account for final state QED and QCD corrections, as well as effects due to nonzero fermion masses, and $\Delta_{ew/\text{QCD}}$ represents the non-factorizable electroweak/QCD corrections.

S-matrix approach to the Z

While most experimental analyses of LEP/SLC data have followed the 'Breit-Wigner' approach, an alternative S-matrix-based analysis is also possible. The Z, like all unstable particles, is associated with a complex pole in the S matrix. The pole position is process-independent and gauge-invariant. The mass, \overline{M}_Z , and width, $\overline{\Gamma}_Z$, can be defined in terms of the pole in the energy plane via [11–14]

$$\overline{s} = \overline{M}_Z^2 - i\overline{M}_Z\overline{\Gamma}_Z \tag{8}$$

leading to the relations

$$\overline{M}_Z = M_Z / \sqrt{1 + \Gamma_Z^2 / M_Z^2}$$

$$\approx M_Z - 34.1 \text{ MeV}$$
(9)

$$\overline{\Gamma}_Z = \Gamma_Z / \sqrt{1 + \Gamma_Z^2 / M_Z^2}$$

$$\approx \Gamma_Z - 0.9 \text{ MeV} . \tag{10}$$

The L3 and OPAL Collaborations at LEP (ACCIARRI 00Q and ABBIENDI 04G) have analyzed their data using the S–matrix approach as defined in Eq. (8), in addition to the conventional one. They observe a downward shift in the Z mass as expected.

Handling the large-angle e^+e^- final state

Unlike other $f\overline{f}$ decay final states of the Z, the e^+e^- final state has a contribution not only from the s-channel but also from the t-channel and s-t interference. The full amplitude is not amenable to fast calculation, which is essential if one has to carry out minimization fits within reasonable computer time. The usual procedure is to calculate the non-s channel part of the cross section separately using the Standard Model programs ALIBABA [15] or TOPAZO [16], with the measured value of $M_{\rm top}$, and $M_{\rm Higgs}=150$ GeV, and add it to the s-channel cross section calculated as for other channels. This leads to two additional sources of error in the analysis: firstly,

the theoretical calculation in ALIBABA itself is known to be accurate to $\sim 0.5\%$, and secondly, there is uncertainty due to the error on $M_{\rm top}$ and the unknown value of $M_{\rm Higgs}$ (100–1000 GeV). These errors are propagated into the analysis by including them in the systematic error on the e^+e^- final state. As these errors are common to the four LEP experiments, this is taken into account when performing the LEP average.

Errors due to uncertainty in LEP energy determination [17–22]

The systematic errors related to the LEP energy measurement can be classified as:

- The absolute energy scale error;
- Energy-point-to-energy-point errors due to the nonlinear response of the magnets to the exciting currents;
- Energy-point-to-energy-point errors due to possible higher-order effects in the relationship between the dipole field and beam energy;
- Energy reproducibility errors due to various unknown uncertainties in temperatures, tidal effects, corrector settings, RF status, etc.

Precise energy calibration was done outside normal datataking using the resonant depolarization technique. Run-time energies were determined every 10 minutes by measuring the relevant machine parameters and using a model which takes into account all the known effects, including leakage currents produced by trains in the Geneva area and the tidal effects due to gravitational forces of the Sun and the Moon. The LEP Energy Working Group has provided a covariance matrix from the determination of LEP energies for the different running periods during 1993–1995 [17].

Choice of fit parameters

The LEP Collaborations have chosen the following primary set of parameters for fitting: M_Z , Γ_Z , $\sigma_{\rm hadron}^0$, $R({\rm lepton})$, $A_{FB}^{(0,\ell)}$, where $R({\rm lepton}) = \Gamma({\rm hadrons})/\Gamma({\rm lepton})$, $\sigma_{\rm hadron}^0 = 12\pi\Gamma(e^+e^-)\Gamma({\rm hadrons})/M_Z^2\Gamma_Z^2$. With a knowledge of these fitted parameters and their covariance matrix, any other parameter can be derived. The main advantage of these parameters is that they form a physics motivated set of parameters with much reduced correlations.

Thus, the most general fit carried out to cross section and asymmetry data determines the **nine parameters**: M_Z , Γ_Z , $\sigma^0_{\rm hadron}$, R(e), $R(\mu)$, $R(\tau)$, $A^{(0,e)}_{FB}$, $A^{(0,\mu)}_{FB}$, $A^{(0,\tau)}_{FB}$. Assumption of lepton universality leads to a **five-parameter fit** determining M_Z , Γ_Z , $\sigma^0_{\rm hadron}$, $R({\rm lepton})$, $A^{(0,\ell)}_{FB}$.

$Combining\ results\ from\ LEP\ and\ SLC\ experiments$

With a steady increase in statistics over the years and improved understanding of the common systematic errors between LEP experiments, the procedures for combining results have evolved continuously [23]. The Line Shape Sub-group of the LEP Electroweak Working Group investigated the effects of these common errors, and devised a combination procedure

for the precise determination of the Z parameters from LEP experiments. Using these procedures, this note also gives the results after combining the final parameter sets from the four experiments, and these are the results quoted as the fit results in the Z listings below. Transformation of variables leads to values of derived parameters like partial decay widths and branching ratios to hadrons and leptons. Finally, transforming the LEP combined nine parameter set to $(M_Z, \Gamma_Z, \sigma_{\rm hadron}^{\circ}, g_A^f, g_V^f, f = e, \mu, \tau)$ using the average values of lepton asymmetry parameters (A_e, A_μ, A_τ) as constraints, leads to the best fitted values of the vector and axial-vector couplings (g_V, g_A) of the charged leptons to the Z.

Brief remarks on the handling of common errors and their magnitudes are given below. The identified common errors are those coming from

- (a) LEP energy-calibration uncertainties, and
- (b) the theoretical uncertainties in (i) the luminosity determination using small angle Bhabha scattering, (ii) estimating the non-s channel contribution to large angle Bhabha scattering, (iii) the calculation of QED radiative effects, and (iv) the parametrization of the cross section in terms of the parameter set used.

Common LEP energy errors

All the collaborations incorporate in their fit the full LEP energy error matrix as provided by the LEP energy group for their intersection region [17]. The effect of these errors is separated out from that of other errors by carrying out fits with energy errors scaled up and down by $\sim 10\%$ and redoing the fits. From the observed changes in the overall error matrix, the covariance matrix of the common energy errors is determined. Common LEP energy errors lead to uncertainties on M_Z , Γ_Z , and $\sigma_{\rm hadron}^{\circ}$ of 1.7, 1.2 MeV, and 0.011 nb, respectively.

$Common\ luminosity\ errors$

BHLUMI 4.04 [24] is used by all LEP collaborations for small-angle Bhabha scattering leading to a common uncertainty in their measured cross sections of 0.061% [25]. BHLUMI does not include a correction for production of light fermion pairs. OPAL explicitly corrects for this effect and reduces their luminosity uncertainty to 0.054%, which is taken fully correlated with the other experiments. The other three experiments among themselves have a common uncertainty of 0.061%.

Common non-s channel uncertainties

The same standard model programs ALIBABA [15] and TOPAZ0 [16] are used to calculate the non-s channel contribution to the large angle Bhabha scattering [26]. As this contribution is a function of the Z mass, which itself is a variable in the fit, it is parametrized as a function of M_Z by each collaboration to properly track this contribution as M_Z varies in the fit. The common errors on R_e and $A_{FB}^{(0,e)}$ are 0.024 and 0.0014 respectively, and are correlated between them.

Common theoretical uncertainties: QED

There are large initial-state photon and fermion pair radiation effects near the Z resonance, for which the best currently

available evaluations include contributions up to $\mathcal{O}(\alpha^3)$. To estimate the remaining uncertainties, different schemes are incorporated in the standard model programs ZFITTER [5], TOPAZ0 [16], and MIZA [27]. Comparing the different options leads to error estimates of 0.3 and 0.2 MeV on M_Z and Γ_Z respectively, and of 0.02% on $\sigma_{\rm hadron}^{\circ}$.

Common theoretical uncertainties: parametrization of lineshape and asymmetries

To estimate uncertainties arising from ambiguities in the model-independent parametrization of the differential cross-section near the Z resonance, results from TOPAZ0 and ZFIT-TER were compared by using ZFITTER to fit the cross sections and asymmetries calculated using TOPAZ0. The resulting uncertainties on M_Z , Γ_Z , $\sigma_{\rm hadron}^{\circ}$, $R({\rm lepton})$, and $A_{FB}^{(0,\ell)}$ are 0.1 MeV, 0.1 MeV, 0.001 nb, 0.004, and 0.0001 respectively.

Thus, the overall theoretical errors on M_Z , Γ_Z , $\sigma_{\rm hadron}^{\circ}$ are 0.3 MeV, 0.2 MeV, and 0.008 nb respectively; on each $R({\rm lepton})$ is 0.004 and on each $A_{FB}^{(0,\ell)}$ is 0.0001. Within the set of three $R({\rm lepton})$'s and the set of three $A_{FB}^{(0,\ell)}$'s, the respective errors are fully correlated.

All the theory-related errors mentioned above utilize Standard Model programs which need the Higgs mass and running electromagnetic coupling constant as inputs; uncertainties on these inputs will also lead to common errors. All LEP collaborations used the same set of inputs for Standard Model calculations: $M_Z = 91.187$ GeV, the Fermi constant $G_F = (1.16637 \pm 0.00001) \times 10^{-5} \text{ GeV}^{-2}$ [28], $\alpha^{(5)}(M_Z) = 1/128.877 \pm 0.090 [29], \quad \alpha_s(M_Z) = 0.119 [30],$ $M_{\rm top}=174.3\pm5.1~{\rm GeV}$ [30] and $M_{\rm Higgs}=150~{\rm GeV}$. The only observable effect, on M_Z , is due to the variation of M_{Higgs} between 100–1000 GeV (due to the variation of the γ/Z interference term which is taken from the Standard Model): M_Z changes by +0.23 MeV per unit change in $\log_{10} M_{\rm Higgs}/{\rm GeV}$, which is not an error but a correction to be applied once $M_{\rm Higgs}$ is determined. The effect is much smaller than the error on M_Z (± 2.1 MeV).

$Methodology\ of\ combining\ the\ LEP\ experimental\ results$

The LEP experimental results actually used for combination are slightly modified from those published by the experiments (which are given in the Listings below). This has been done in order to facilitate the procedure by making the inputs more consistent. These modified results are given explicitly in [23]. The main differences compared to the published results are (a) consistent use of ZFITTER 6.23 and TOPAZ0 (the published ALEPH results used ZFITTER 6.10); (b) use of the combined energy-error matrix, which makes a difference of 0.1 MeV on the M_Z and Γ_Z for L3 only as at that intersection the RF modeling uncertainties are the largest.

Thus, nine-parameter sets from all four experiments with their covariance matrices are used together with all the common errors correlations. A grand covariance matrix, V, is constructed and a combined nine-parameter set is obtained by

Z

minimizing $\chi^2 = \Delta^T V^{-1} \Delta$, where Δ is the vector of residuals of the combined parameter set to the results of individual experiments. Imposing lepton universality in the combination results in the combined five parameter set.

Study of $Z \to b\overline{b}$ and $Z \to c\overline{c}$

In the sector of c- and b-physics, the LEP experiments have measured the ratios of partial widths $R_b = \Gamma(Z \to b\bar{b})/\Gamma(Z \to b\bar{b})$ hadrons), and $R_c = \Gamma(Z \to c\overline{c})/\Gamma(Z \to \text{hadrons})$, and the forward-backward (charge) asymmetries A_{FB}^{bb} and $A_{FB}^{c\bar{c}}$. The SLD experiment at SLC has measured the ratios R_c and R_b and, utilizing the polarization of the electron beam, was able to obtain the final state coupling parameters A_b and A_c from a measurement of the left-right forward-backward asymmetry of b- and c-quarks. The high precision measurement of R_c at SLD was made possible owing to the small beam size and very stable beam spot at SLC, coupled with a highly precise CCD pixel detector. Several of the analyses have also determined other quantities, in particular the semileptonic branching ratios, $B(b \to \ell^-)$, $B(b \to c \to \ell^+)$, and $B(c \to \ell^+)$, the average timeintegrated $B^0\overline{B}^0$ mixing parameter $\overline{\chi}$ and the probabilities for a c-quark to fragment into a D^+ , a D_s , a D^{*+} , or a charmed baryon. The latter measurements do not concern properties of the Z boson, and hence they do not appear in the Listing below. However, for completeness, we will report at the end of this minireview their values as obtained fitting the data contained in the Z section. All these quantities are correlated with the electroweak parameters, and since the mixture of b hadrons is different from the one at the $\Upsilon(4S)$, their values might differ from those measured at the $\Upsilon(4S)$.

All the above quantities are correlated to each other since:

- Several analyses (for example the lepton fits) determine more than one parameter simultaneously;
- Some of the electroweak parameters depend explicitly on the values of other parameters (for example R_b depends on R_c);
- Common tagging and analysis techniques produce common systematic uncertainties.

The LEP Electroweak Heavy Flavour Working Group has developed [31] a procedure for combining the measurements taking into account known sources of correlation. The combining procedure determines fourteen parameters: the six parameters of interest in the electroweak sector, R_b , R_c , $A_{FB}^{b\bar{b}}$, $A_{FB}^{c\bar{c}}$, A_b and A_c and, in addition, $B(b \to \ell^-)$, $B(b \to c \to \ell^+)$, $B(c \to \ell^+)$, $\overline{\chi}$, $f(D^+)$, $f(D_s)$, $f(c_{\text{baryon}})$ and $P(c \to D^{*+}) \times B(D^{*+} \to \pi^+ D^0)$, to take into account their correlations with the electroweak parameters. Before the fit both the peak and off-peak asymmetries are translated to the common energy $\sqrt{s} = 91.26$ GeV using the predicted energy-dependence from ZFITTER [5].

$Summary\ of\ the\ measurements\ and\ of\ the\ various\ kinds$ of analysis

The measurements of R_b and R_c fall into two classes. In the first, named single-tag measurement, a method for selecting b and c events is applied and the number of tagged events is counted. A second technique, named double-tag measurement, has the advantage that the tagging efficiency is directly derived from the data thereby reducing the systematic error on the measurement.

The measurements in the b- and c-sector can be essentially grouped in the following categories:

- Lifetime (and lepton) double-tagging measurements of R_b. These are the most precise measurements of R_b and obviously dominate the combined result. The main sources of systematics come from the charm contamination and from estimating the hemisphere b-tagging efficiency correlation;
- Analyses with $D/D^{*\pm}$ to measure R_c . These measurements make use of several different tagging techniques (inclusive/exclusive double tag, exclusive double tag, reconstruction of all weakly decaying charmed states) and no assumptions are made on the energy-dependence of charm fragmentation;
- A measurement of R_c using single leptons and assuming $B(b \to c \to \ell^+)$;
- Lepton fits which use hadronic events with one or more leptons in the final state to measure the asymmetries $A_{FB}^{b\bar{b}}$ and $A_{FB}^{c\bar{c}}$. Each analysis usually gives several other electroweak parameters. The dominant sources of systematics are due to lepton identification, to other semileptonic branching ratios and to the modeling of the semileptonic decay;
- Measurements of A^{b\bar{b}}_{FB} using lifetime tagged events with a hemisphere charge measurement. These measurements dominate the combined result;
- Analyses with $D/D^{*\pm}$ to measure $A_{FB}^{c\overline{c}}$ or simultaneously $A_{FB}^{b\overline{b}}$ and $A_{FB}^{c\overline{c}}$;
- Measurements of A_b and A_c from SLD, using several tagging methods (lepton, kaon, D/D^* , and vertex mass). These quantities are directly extracted from a measurement of the left–right forward–backward asymmetry in $c\overline{c}$ and $b\overline{b}$ production using a polarized electron beam.

$Averaging\ procedure$

All the measurements are provided by the LEP and SLD Collaborations in the form of tables with a detailed breakdown of the systematic errors of each measurement and its dependence on other electroweak parameters.

The averaging proceeds via the following steps:

• Define and propagate a consistent set of external inputs such as branching ratios, hadron lifetimes, fragmentation models *etc*. All the measurements are checked to ensure that all use a common set of assumptions (for instance, since the QCD corrections for the forward–backward asymmetries are strongly dependent on the experimental conditions, the data are corrected before combining);

Among the non-electroweak observables, the B semileptonic

- Form the full (statistical and systematic) covariance matrix of the measurements. The systematic correlations between different analyses are calculated from the detailed error breakdown in the measurement tables. The correlations relating several measurements made by the same analysis are also used:
- Take into account any explicit dependence of a
 measurement on the other electroweak parameters.
 As an example of this dependence, we illustrate
 the case of the double-tag measurement of R_b,
 where c-quarks constitute the main background.
 The normalization of the charm contribution is not
 usually fixed by the data and the measurement of
 R_b depends on the assumed value of R_c, which can
 be written as:

$$R_b = R_b^{\text{meas}} + a(R_c) \frac{(R_c - R_c^{\text{used}})}{R_c} , \qquad (11)$$

where R_b^{meas} is the result of the analysis which assumed a value of $R_c = R_c^{\text{used}}$ and $a(R_c)$ is the constant which gives the dependence on R_c ;

• Perform a χ^2 minimization with respect to the combined electroweak parameters.

After the fit the average peak asymmetries $A_{FB}^{c\bar{c}}$ and $A_{FB}^{b\bar{b}}$ are corrected for the energy shift from 91.26 GeV to M_Z and for QED (initial state radiation), γ exchange, and γZ interference effects, to obtain the corresponding pole asymmetries $A_{FB}^{0,c}$ and $A_{FB}^{0,c}$.

This averaging procedure, using the fourteen parameters described above, and applied to the data contained in the Z particle listing below, gives the following results (where the last 8 parameters do not depend directly on the Z):

$$R_b^0 = 0.21629 \pm 0.00066$$

$$R_c^0 = 0.1721 \pm 0.0030$$

$$A_{FB}^{0,b} = 0.0992 \pm 0.0016$$

$$A_{FB}^{0,c} = 0.0707 \pm 0.0035$$

$$A_b = 0.923 \pm 0.020$$

$$A_c = 0.670 \pm 0.027$$

$$B(b \to \ell^{-}) = 0.1071 \pm 0.0022$$

$$B(b \to c \to \ell^{+}) = 0.0801 \pm 0.0018$$

$$B(c \to \ell^{+}) = 0.0969 \pm 0.0031$$

$$\overline{\chi} = 0.1250 \pm 0.0039$$

$$f(D^{+}) = 0.235 \pm 0.016$$

$$f(D_{s}) = 0.126 \pm 0.026$$

$$f(c_{\text{baryon}}) = 0.093 \pm 0.022$$

$$P(c \to D^{*+}) \times B(D^{*+} \to \pi^{+}D^{0}) = 0.1622 \pm 0.0048$$

branching fraction $B(b \to \ell^-)$ is of special interest, since the dominant error source on this quantity is the dependence on the semileptonic decay model for $b \to \ell^-$, with $\Delta B(b \to \ell^-)_{b \to \ell^- - \mathrm{model}} = 0.0012$. Extensive studies have been made to understand the size of this error. Among the electroweak quantities, the quark asymmetries with leptons depend also on the semileptonic decay model, while the asymmetries using other methods usually do not. The fit implicitly requires that the different methods give consistent results and this effectively constrains the decay model, and thus reduces in principle the error from this source in the fit result.

To obtain a conservative estimate of the modelling error, the above fit has been repeated removing all asymmetry measurements. The results of the fit on B–decay related observables are [23]: $B(b \to \ell^-) = 0.1069 \pm 0.0022$, with $\Delta B(b \to \ell^-)_{b\to\ell^--\mathrm{model}} = 0.0013$, $B(b \to c \to \ell^+) = 0.0802 \pm 0.0019$ and $\overline{\chi} = 0.1259 \pm 0.0042$.

Z MASS

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). The fit is performed using the Z mass and width, the Z hadronic pole cross section, the ratios of hadronic to leptonic partial widths, and the Z pole forward-backward lepton asymmetries. This set is believed to be most free of correlations.

The Z-boson mass listed here corresponds to the mass parameter in a Breit-Wigner distribution with mass dependent width. The value is 34 MeV greater than the real part of the position of the pole (in the energysquared plane) in the Z-boson propagator. Also the LEP experiments have generally assumed a fixed value of the $\gamma-Z$ interferences term based on the standard model. Keeping this term as free parameter leads to a somewhat larger error on the fitted Z mass. See ACCIARRI 00Q and ABBIENDI 04G for a detailed investigation of both these issues

 $^{^{}m 1}$ ABBIENDI 01A error includes approximately 2.3 MeV due to statistics and 1.8 MeV due to LEP energy uncertainty.

⁵ ABBIENDI 04G obtain this result using the S-matrix formalism for a combined fit to their cross section and asymmetry data at the $\it Z$ peak and their data at 130–209 GeV. The authors have corrected the measurement for the 34 MeV shift with respect to the

 6 ACHARD 04c select $e^+e^- o Z\gamma$ events with hard initial-state radiation. Z decays to $q\overline{q}$ and muon pairs are considered. The fit results obtained in the two samples are found consistent to each other and combined considering the uncertainty due to ISR modelling as fully correlated.

⁷ACCIARRI 00Q interpret the s-dependence of the cross sections and lepton forwardbackward asymmetries in the framework of the S-matrix formalism. They fit to their cross section and asymmetry data at high energies, using the results of S-matrix fits to Z-peak data (ACCIARRI 00ć) as constraints. The 130–189 GeV data constrains the γ/Z interference term. The authors have corrected the measurement for the 34.1 MeV shift with respect to the Breit-Wigner fits. The error contains a contribution of ± 2.3 MeV due to the uncertainty on the γZ interference.

with the ACTON 93D data and perform a fit using an S-matrix formalism. As expected, this result is below the mass values obtained with the standard Breit-Wigner parametriza-

Eithers fit through W/Z mass ratio given in the W Particle Listings. The ALITTI 92B systematic error (± 0.93) has two contributions: one (± 0.92) cancels in m_W/m_Z and one (± 0.12) is noncancelling. These were added in quadrature.

Z WIDTH

 $^{^{13}}$ ABBIENDI 01A error includes approximately 3.6 MeV due to statistics, 1 MeV due to event selection systematics, and 1.3 MeV due to LEP energy uncertainty, 14 The error includes 1.2 MeV due to LEP energy uncertainty.

²The error includes 1.6 MeV due to LEP energy uncertainty.

³The error includes 1.8 MeV due to LEP energy uncertainty.

⁴BARATE 00c error includes approximately 2.4 MeV due to statistics, 0.2 MeV due to experimental systematics, and 1.7 MeV due to LEP energy uncertainty.

 $^{^{10}}$ First error of ABE 89 is combination of statistical and systematic contributions; second is mass scale uncertainty

 $^{^{11}\}mathrm{ABRAMS}$ 89B uncertainty includes 35 MeV due to the absolute energy measurement.

 $^{^{12}}$ ALBAJAR 89 result is from a total sample of 33 $Z
ightarrow \ e^+ \, e^-$ events.

 $^{^{15}}$ The error includes 1.3 MeV due to LEP energy uncertainty.

¹⁶ BARATE 00c error includes approximately 3.8 MeV due to statistics, 0.9 MeV due to experimental systematics, and 1.3 MeV due to LEP energy uncertainty.

¹⁷ ABBIENDI 046 obtain, this result using the S-matrix formalism for a combined fit to their cross section and asymmetry data at the Z peak and their data at 130-209 GeV. The authors have corrected the measurement for the 1 MeV shift with respect to the Breit-Wigner fits.

¹⁸ACCIARRI 00Q interpret the s-dependence of the cross sections and lepton forwardbackward asymmetries in the framework of the S-matrix formalism. They fit to their

cross section and asymmetry data at high energies, using the results of S-matrix fits to Z-peak data (ACCIARRI 00c) as constraints. The 130–189 GeV data constrains the γ/Z interference term. The authors have corrected the measurement for the 0.9 MeV shift with respect to the Breit-Wigner fits.

 $^{19}\mathsf{ABREU}$ 96R obtain this value from a study of the interference between initial and final state radiation in the process $e^+e^- \rightarrow Z \rightarrow \mu^+\mu^-$

20 ABRAMS 89B uncertainty includes 50 MeV due to the miniSAM background subtraction $21\,\mathrm{ALBA\,JAR}$ 89 result is from a total sample of 33 $Z \to e^+e^-$ events

22 Quoted values of ANSARI 87 are from direct fit. Ratio of Z and W production gives either $\Gamma(Z) < (1.09 \pm 0.07) \times \Gamma(W)$, CL = 90% or $\Gamma(Z) = (0.82 \stackrel{+}{-} 0.14 \pm 0.06) \times \Gamma(W)$. Assuming Standard-Model value $\Gamma(W)=2.65$ GeV then gives $\Gamma(Z)<2.89\pm0.19$ or $=2.17^{+0.50}_{-0.37}\pm0.16$.

 $\Gamma(\ell^+\ell^-)$ Γ_4

In our fit $\Gamma(\ell^+\ell^-)$ is defined as the partial Z width for the decay into a pair of massless charged leptons. This parameter is not directly used in the 5-parameter fit assuming lepton universality but is derived using the fit results. See the note "The $\it Z$ boson" and ref. LEP-SLC 06.

- 44 ABE 05F use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $c\overline{c}$ events using a double tag method. The single c-tag is obtained with a neural network trained to perform flavor discrimination using as input several signatures (corrected secondary vertex mass, vertex decay length, multiplicity and total momentum of the hemisphere). A multitag approach is used, defining 4 regions of the output value of the neural network and $R_{\rm c}$ is extracted from a simultaneous fit to the count rates of the 4 different tags. The quoted systematic error includes an uncertainty of ± 0.0006 due to the uncertainty on R_b
- 45 ABREU 00 obtain this result properly combining the measurement from the D^{*+} production rate $(R_C=0.1610\pm0.0104\pm0.0077\pm0.0043~(BR))$ with that from the overall charm counting $(R_C=0.1692\pm0.0047\pm0.0063\pm0.0074~(BR))$ in $c\overline{c}$ events. The systematic error includes an uncertainty of ±0.0054 due to the uncertainty on the charmed hadron branching fractions.
- $^{46}\,\mathrm{BARATE}$ 00B use exclusive decay modes to independently determine the quantities $R_C imes f(c o X), X = D^0, D^+, D_S^+$, and A_C . Estimating $R_C imes f(c o \Xi_C/\Omega_C) = 0.0034$, they simply sum over all the charm decays to obtain $R_C = 0.1738 \pm 0.0047 \pm 0.0088 \pm 0.0075 (BR)$. This is combined with all previous ALEPH measurements (BARATE 98T and BUSKULIC 946, $R_{c}=0.1681\pm0.0054\pm0.0062$) to obtain the quoted value.
- 47 ACKERSTAFF 98E use an inclusive/exclusive double tag. In one jet $D^{*\pm}$ mesons are exclusively reconstructed in several decay channels and in the opposite jet a slow pion copposite charge inclusive $D^{*\pm}$) tag is used. The b content of this sample is measured by the simultaneous detection of a lepton in one jet and an inclusively reconstructed $D^{*\pm}$ meson in the opposite jet. The systematic error includes an uncertainty of ± 0.006 due to the external branching ratios.
- 48 ALEXANDER 96R obtain this value via direct charm counting, summing the partial contributions from ${\it D}^0$, ${\it D}^+$, ${\it D}^+_{\it S}$, and ${\it \Lambda}^+_{\it C}$, and assuming that strange-charmed baryons account for the 15% of the Λ_C^+ production. An uncertainty of ± 0.005 due to the uncertainties in the charm hadron branching ratios is included in the overall systematics.
- 49 ABREU 95D perform a maximum likelihood fit to the combined ρ and ρ_T distributions of single and dilepton samples. The second error includes an uncertainty of ± 0.0124 due to models and branching ratios.

$R_b = \Gamma(b\overline{b})/\Gamma(\text{hadrons})$

OUR FIT is obtained by a simultaneous fit to several c- and b-quark measurements as explained in the note "The Z boson" and ref. LEP-SLC 06.

The Standard Model predicts R_b =0.21581 for m_t =174.3 GeV and M_H =150 GeV.

- $^{50}\,\mathrm{ABE}$ 05F use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $b\overline{b}$ events using a double tag method. The single b-tag is obtained with a neural network trained to perform flavor discrimination using as input several signatures (corrected secondary vertex mass, vertex decay length, multiplicity and total momentum of the hemisphere; the key tag is obtained requiring the secondary vertex corrected mass to be above the D-meson mass). ABE 05F obtain $R_b=0.21604\pm0.00098\pm0.00074$ where the systematic error includes an uncertainty of ±0.00012 due to the uncertainty on $R_c.$ The value reported here is obtained properly combining with ABE 98D. The quoted systematic error includes an uncertainty of ± 0.00012 due to the uncertainty on $R_c.$
- 51 ACCIARRI 00 obtain this result using a double-tagging technique, with a high p_T lepton
- tag and an impact parameter tag in opposite hemispheres. 52 ABBIENDI 998 tag $Z \rightarrow b\overline{b}$ decays using leptons and/or separated decay vertices. The b-tagging efficiency is measured directly from the data using a double-tagging technique.
- 53 ABREU 998 obtain this result combining in a multivariate analysis several tagging meth-ods (impact parameter and secondary vertex reconstruction, complemented by event shape variables). For R_c different from its Standard Model value of 0.172, R_b varies as $-0.024 \times (R_c - 0.172)$.
- ⁵⁴ BARATE 97F combine the lifetime-mass hemisphere tag (BARATE 97E) with event shape information and lepton tag to identify $Z \rightarrow b\overline{b}$ candidates. They further use c- and ud s-selection tags to identify the background. For R_C different from its Standard Model value of 0.172, R_D varies as $-0.019 \times (R_C 0.172)$.
- 55 ABREU 95D perform a maximum likelihood fit to the combined p and p_T distributions of single and dilepton samples. The second error includes an uncertainty of ± 0.0023 due to models and branching ratios.
- 56 BUSKULIC 94G perform a simultaneous fit to the ho and p_T spectra of both single and
- 57 JACOBSEN 91 tagged $b\overline{b}$ events by requiring coincidence of \geq 3 tracks with significant impact parameters using vertex detector. Systematic error includes lifetime and decay uncertainties (± 0.014)

| seen | ⁹⁸ ABDALLAH | 05 C | DLPH | $E_{\rm cm}^{ee} = 88-94 {\rm GeV}$ |
| seen | ⁹⁹ BUSKULIC | 96T | ALEP | E ee = 88-94 GeV |
| seen | 100 ABREU | 95∨ | DLPH | E ^{ee} _{cm} = 88-94 GeV |

 98 ABDALLAH 05c searched for the beauty strange baryon \varXi_b in the inclusive semileptonic decay channel $\Xi_b \to \Xi^- \ell^- \overline{\nu}_\ell X$. Evidence for the Ξ_b production is seen from the observation of $\Xi^{\tilde{\mp}}$ production accompanied by a lepton of the same sign. From the excess of "right-sign" pairs $\Xi^{\mp}\ell^{\mp}$ compared to "wrong-sign" pairs $\Xi^{\mp}\ell^{\pm}$ the production rate is measured to be $B(b \to \Xi_b) \times B(\Xi_b \to \Xi^{-}\ell^{-}X) = (3.0 \pm 1.0 \pm 0.3) \times 10^{-4}$ per lepton species, averaged over electrons and muons.

99 BUSKULIC 96T investigate Ξ -lepton correlations and find a significant excess of "rightsign" pairs $\Xi^\mp\ell^\mp$ compared to "wrong-sign" pairs $\Xi^\mp\ell^\pm$. This excess is interpreted as evidence for Ξ_b semileptonic decay. The measured product branching ratio is B($b\to 0$) $\Xi_b) imes {\sf B}(\Xi_b o X_c X \ell^- \overline{
u}_\ell) imes {\sf B}(X_c o \Xi^- X') = (5.4 \pm 1.1 \pm 0.8) imes 10^{-4}$ per lepton species, averaged over electrons and muons, with X_c a charmed baryon.

 100 ABREU 95v observe an excess of "right-sign" pairs $\varXi^{\mp}\ell^{\bar{\mp}}$ compared to "wrong-sign" pairs $\varXi^\mp\ell^\pm$ in jets: this excess is interpreted as evidence for the beauty strange baryon Ξ_b production, with $\Xi_b \to \Xi^- \ell^- \overline{\nu}_\ell X$. They find that the probability for this signal to because from non b-baryon decays is less than 5×10^{-4} and that Λ_b decays can account for less than 10% of these events. The Ξ_b production rate is then measured to be B($b\to$ $\Xi_b)\times {\rm B}(\Xi_b\to\Xi^-\ell^-X)=(5.9\pm2.1\pm1.0)\times10^{-4}$ per lepton species, averaged over electrons and muons.

 $\Gamma(b ext{-baryon X})/\Gamma(\text{hadrons})$ "OUR EVALUATION" is obtained using our current values for $f(b\to b\text{-baryon})$ and $R_b = \Gamma(b\overline{b})/\Gamma(hadrons)$. We calculate $\Gamma(b$ -baryon X)/ $\Gamma(hadrons) = R_b \times f(b \to b$ -baryon). The decay fraction $f(b \to b$ -baryon) was provided by the Heavy Flavor Averaging Group (HFAG, http://www.slac.stanford.edu/xorg/hfag/osc/PDG_2009). VALUE DOCUMENT ID TECN COMMENT

| | | | | |

¹¹¹ BEDDALL 09 analyse 3.2 million hadronic Z decays as archived by ALEPH collaboration and report a value of $2.59 \pm 0.03 \pm 0.15 \pm 0.04$. The first error is statistical, the second systematic, and the third arises from extrapolation to full phase space. We combine the systematic errors in quadrature.

Z HADRONIC POLE CROSS SECTION

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The $\it Z$ boson" and ref. LEP-SLC 06). This quantity is defined as

$$\sigma_h^0 = \frac{12\pi}{M_Z^2} \, \frac{\Gamma(e^+e^-) \, \Gamma(\text{hadrons})}{\Gamma_Z^2}$$

It is one of the parameters used in the Z lineshape fit.

 $^{^{126}\}mathsf{ABB}\mathsf{IENDI}$ 01A error includes approximately 0.031 due to statistics, 0.033 due to event selection systematics, $0.029~\mathrm{due}$ to uncertainty in luminosity measurement, and $0.011~\mathrm{due}$ to LEP energy uncertainty.

Z VECTOR COUPLINGS

These quantities are the effective vector couplings of the Z to charged leptons. Their magnitude is derived from a measurement of the Z lineshape and the forward-backward lepton asymmetries as a function of energy around the Z mass. The relative sign among the vector to axial-vector couplings is obtained from a measurement of the Z asymmetry parameters, $A_e,\,A_\mu,\,{\rm and}\,\,A_\tau.$ By convention the sign of g^e_A is fixed to be negative (and opposite to that of g^{ν_ℓ} obtained using ν_e scattering measurements). For the light quarks, the sign of the couplings is assigned consistently with this assumption. The fit values quoted below correspond to global nine- or five-parameter fits to lineshape, lepton forward-backward asymmetry, and A_e , A_μ , and A_τ measurements. See the note "The Z boson" and ref. LEP-SLC 06 for details. Where $p\overline{p}$ and ep data is quoted, OUR FIT value corresponds to a weighted average of this with the LEP/SLD fit result.

These results are used to obtain the vector and axial-vector couplings of the Z to the light quarks, assuming the electron couplings are as predicted by the ${\sf Standard}$ Model. Higher order radiative corrections have not been taken into account.

Z COUPLINGS TO NEUTRAL LEPTONS

Averaging over neutrino species, the invisible Z decay width determines the effective neutrino coupling $g^{
u_\ell}$. For $g^{
u_\ell}$ and $g^{
u_\mu}$, $u_e\,e$ and $u_\mu\,e$ scattering results are combined with g_A^e and g_V^e measurements at the Zmass to obtain $g^{
u_{\ell}}$ and $g^{
u\mu}$ following NOVIKOV 93c.

Z ASYMMETRY PARAMETERS

For each fermion-antifermion pair coupling to the Z these quantities are

$$A_f = \frac{2g_V^f g_A^f}{(g_V^f)^2 + (g_A^f)^2}$$

where g_V^f and g_A^f are the effective vector and axial-vector couplings. For their relation to the various lepton asymmetries see the note "The Z boson" and ref. LEP-SLC 06.

Using polarized beams, this quantity can also be measured as $(\sigma_L - \sigma_R)/\left(\sigma_L + \sigma_R\right)$, where σ_L and σ_R are the e^+e^- production cross sections for Z bosons produced with left-handed and right-handed electrons respectively.

- 186 ABE 05 use hadronic Z decays collected during 1996–98 to obtain an enriched sample of $^b\bar{b}$ events tagging on the invariant mass of reconstructed secondary decay vertices. The charge of the underlying b-quark is obtained with an algorithm that takes into account the net charge of the vertex as well as the charge of tracks emanating from the vertex and identified as kaons. This yields (25 917 events) $A_b=0.9173\pm0.0184\pm0.0173$. Taking into account all correlations with earlier results reported in ABE 03F, ABE 02G and ABE 991, they obtain the quoted overall SLD results.
- and ABE 99t, they obtain the quoted overlain SED 153m.

 187 ABE 03F obtain an enriched sample of $b\overline{b}$ events tagging on the invariant mass of a 3-dimensional topologically reconstructed secondary decay. The charge of the underlying b quark is obtained using a self-calibrating track-charge method. For the 1996–1998 data sample they measure $A_b = 0.906 \pm 0.022 \pm 0.023$. The value quoted here is obtained combining the above with the result of ABE 98I (1993–1995 data sample).
- 188 ABE 026 tag b and c quarks through their semileptonic decays into electrons and muons. A maximum likelihood fit is performed to extract simultaneously A_b and A_C .
- 189 ABE 99L obtain an enriched sample of $b\overline{b}$ events tagging with an inclusive vertex mass cut. For distinguishing b and \overline{b} quarks they use the charge of identified K^\pm .

TRANSVERSE SPIN CORRELATIONS IN $Z \rightarrow \tau^+ \tau^-$

The correlations between the transverse spin components of $\tau^+\tau^-$ produced in Z decays may be expressed in terms of the vector and axial-vector couplings:

$$\begin{split} C_{TT} &= \frac{|g_A^T|^2 - |g_V^T|^2}{|g_A^T|^2 + |g_V^T|^2} \\ C_{TN} &= -2 \frac{|g_A^T||g_V^T|}{|g_A^T|^2 + |g_V^T|^2} \sin(\Phi_{g_V^T} - \Phi_{g_A^T}) \end{split}$$

 C_{TT} refers to the transverse-transverse (within the collision plane) spin correlation and C_{TN} refers to the transverse-normal (to the collision plane) spin correlation.

The longitudinal au polarization $P_{ au} \; (= -A_{ au})$ is given by:

$$P_{\tau} = -2 \frac{|g_{A}^{\tau}||g_{V}^{\tau}|}{|g_{A}^{\tau}|^{2} + |g_{V}^{\tau}|^{2}} \cos(\Phi_{g_{V}^{\tau}} - \Phi_{g_{A}^{\tau}})$$

Here Φ is the phase and the phase difference $\Phi_{\mathcal{G}_V^{\mathcal{T}}}-\Phi_{\mathcal{G}_A^{\mathcal{T}}}$ can be obtained using both the measurements of $C_{\mathcal{TN}}$ and $P_{\mathcal{T}}.$

FORWARD-BACKWARD $e^+e^- \rightarrow f\overline{f}$ CHARGE ASYMMETRIES

These asymmetries are experimentally determined by tagging the respective lepton or quark flavor in $e^+\,e^-$ interactions. Details of heavy flavor (c- or b-quark) tagging at LEP are described in the note on "The Z boson" and ref. LEP-SLC 06. The Standard Model predictions for LEP data have been (re)computed using the ZFITTER package (version 6.36) with input parameters M_Z =91.187 GeV, $M_{\rm top}$ =174.3 GeV, $M_{\rm Higgs}$ =150 GeV, α_S =0.119, $\alpha^{(5)}$ (M_Z)= 1/128.877 and the Fermi constant G_F =1.16637 \times 10 $^{-5}$ GeV $^{-2}$ (see the note on "The Z boson" for references). For non-LEP data the Standard Model predictions are as given by the authors of the respective publications.

– $A_{FB}^{(0,e)}$ CHARGE ASYMMETRY IN $e^+\,e^ightarrow\,e^+\,e^-$ -

OUR FIT is obtained using the fit procedure and correlations as determined by the LEP Electroweak Working Group (see the note "The Z boson" and ref. LEP-SLC 06). For the Z peak, we report the pole asymmetry defined by $(3/4)A_{\rm e}^2$ as determined by the nine-parameter fit to cross-section and lepton forward-backward asymmetry data.

- ²⁰²BACALA 89 systematic error is about 5%.

– $A_{FB}^{(0,\ell)}$ CHARGE ASYMMETRY IN $e^+\,e^ightarrow\,\ell^+\ell^-$ –

For the Z peak, we report the pole asymmetry defined by $(3/4)A_{\ell}^2$ as determined by the five-parameter fit to cross-section and lepton forwardbackward asymmetry data assuming lepton universality. For details see the note "The $\it Z$ boson" and ref. LEP-SLC 06.

 206 ABREU 00B tag the presence of an s quark requiring a high-momentum-identified charged kaon. The s-quark pole asymmetry is extracted from the charged-kaon asymmetry taking the expected d- and u-quark asymmetries from the Standard Model and using the measured values for the c- and b-quark asymmetries.

207 ACKERSTAFF 97T measure the forward-backward asymmetry of various fast hadrons made of light quarks. Then using SU(2) isospin symmetry and flavor independence for down and strange quarks authors solve for the different quark types. The value reported here corresponds then to the forward-backward asymmetry for "down-type" quarks.

ANOMALOUS $ZZ\gamma$, $Z\gamma\gamma$, AND ZZV COUPLINGS

Revised March 2012 by M.W. Grünewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

In on-shell $Z\gamma$ production, deviations from the Standard Model for the $Z\gamma\gamma^*$ and $Z\gamma Z^*$ couplings may be described in terms of 8 parameters, h_i^V ($i=1,4;\ V=\gamma,Z$) [1]. The parameters h_i^V describe the $Z\gamma\gamma^*$ couplings and the parameters h_i^Z the $Z\gamma Z^*$ couplings. In this formalism h_1^V and h_2^V lead to CP-violating and h_3^V and h_4^V to CP-conserving effects. All these anomalous contributions to the cross section increase rapidly with center-of-mass energy. In order to ensure unitarity, these parameters are usually described by a form-factor representation, $h_i^V(s) = h_{io}^V/(1+s/\Lambda^2)^n$, where Λ is the energy scale for the manifestation of a new phenomenon and n is a sufficiently large power. By convention one uses n=3 for $h_{1,3}^V$ and n=4 for $h_{2,4}^V$. Usually limits on h_i^V 's are put assuming some value of Λ , sometimes ∞ .

In on-shell ZZ production, deviations from the Standard Model for the $ZZ\gamma^*$ and ZZZ^* couplings may be described by

means of four anomalous couplings f_i^V $(i=4,5;V=\gamma,Z)$ [2]. As above, the parameters f_i^γ describe the $ZZ\gamma^*$ couplings and the parameters f_i^Z the ZZZ^* couplings. The anomalous couplings f_5^V lead to violation of C and P symmetries while f_4^V introduces CP violation. Also here, formfactors depending on a scale Λ are used.

All these couplings h_i^V and f_i^V are zero at tree level in the Standard Model; they are measured in e^+e^- , $p\bar{p}$ and pp collisions at LEP, Tevatron and LHC.

227 AALTONEN 11s study $Z\gamma$ events in $p\overline{p}$ interactions at $\sqrt{s}=1.96$ TeV with integrated luminosity 5.1 fb $^{-1}$ for $Z\to e^+e^-/\mu^+\mu^-$ and 4.9 fb $^{-1}$ for $Z\to \nu\overline{\nu}$. For the charged lepton case, the two leptons must be of the same flavor with the transverse momentum/energy of one >20 GeV and the other >10 GeV. The isolated photon must have $E_T>50$ GeV. They observe 91 events with 87.2 \pm 7.8 events expected from standard model processes. For the $\nu\overline{\nu}$ case they require solitary photons with $E_T>25$ GeV and missing $E_T>25$ GeV and observe 85 events with standard model expectation of 85.9 \pm 5.6 events. Taking the form factor $\Lambda=1.5$ TeV they derive 95% C.L. limits as $|h_3^{\gamma}, z''|<0.022$ and $|h_4^{\gamma}, z''|<0.0009$.

228 CHATRCHYAN 11M study $Z\gamma$ production in $\rho\rho$ collisions at $\sqrt{s}=7$ TeV using 36 pb⁻¹ $\rho\rho$ data, where the Z decays to e^+e^- or $\mu^+\mu^-$. The total cross sections are measured for photon transverse energy $E_T^\gamma>10$ GeV and spatial separation from charged leptons in the plane of pseudo rapidity and azimuthal angle $\Delta R(\ell,\gamma)>0.7$ with the dilepton invariant mass requirement of $M_{\ell\ell}>50$ GeV. The number of $e^+e^-\gamma$ and $\mu^+\mu^-\gamma$ candidates is 81 and 90 with estimated backgrounds of 20.5 ± 2.5 and 27.3 ± 3.2 events respectively. The 95% CL limits for $ZZ\gamma$ couplings are $-0.05< h_3^Z<0.06$ and $-0.0005< h_4^Z<0.0005$, and for $Z\gamma\gamma$ couplings are $-0.07< h_3^\gamma<0.07$ and $-0.0005< h_4^\gamma<0.0006$.

 229 ABAZOV 09L study $Z\gamma,\,Z\to\nu\overline{\nu}$ production in $\rho\overline{\rho}$ collisions at 1.96 TeV C.M. energy. They select 51 events with a photon of transverse energy E_T larger than 90 GeV, with an expected background of 17 events. Based on the photon E_T spectrum and including also Z decays to charged leptons (from ABAZOV 07M), the following 95% CL limits are reported: $|h_{30}^{\gamma}|<0.033,\,|h_{40}^{\gamma}|<0.0017,\,|h_{30}^{\gamma}|<0.0017,\,|h_{30}^{\gamma}|<0.0017$

230 ABAZOV 07M use 968 $p\overline{p}\to e^+e^-/\mu^+\mu^-\gamma X$ candidates, at 1.96 TeV center of mass energy, to tag $p\overline{p}\to Z\gamma$ events by requiring $E_T(\gamma)>7$ GeV, lepton-gamma separation $\Delta R_{\ell\gamma}>0.7$, and di-lepton invariant mass >30 GeV. The cross section is in agreement with the SM prediction. Using these $Z\gamma$ events they obtain 95% C.L. limits on each h_i^V , keeping all others fixed at their SM values. They report: $-0.083 < h_{20}^Z < 0.082, -0.0053 < h_{40}^Z < 0.0054, -0.085 < h_{30}^\gamma < 0.084, -0.0053 < h_{40}^\gamma < 0.0054,$

 $\begin{array}{lll} 0.082, \, -0.0053 < h_{4Q}^{Z} < 0.0054, \, -0.085 < h_{3Q}^{\gamma} < 0.084, \, -0.0053 < h_{4Q}^{\gamma} < 0.0054, \\ \text{for the form factor scale } \Lambda = 1.2 \,\, \text{TeV}. \\ 231 \,\, \text{Using data collected at } \sqrt{s} = 183-208, \,\, \text{ABDALLAH 07c select } 1,877 \,\, e^+ e^- \rightarrow \,\,\, Z\gamma \\ \text{events with } Z \rightarrow q \overline{q} \,\, \text{or } \nu \overline{\nu}, \,\, 171 \,\, e^+ e^- \rightarrow \,\,\, ZZ \,\, \text{events with } Z \rightarrow q \overline{q} \,\, \text{or lepton pair} \\ \text{(except an explicit τ pair), and } 74 \,\, e^+ e^- \rightarrow \,\,\, Z\gamma^* \,\, \text{events with a } q \, \overline{q} \,\, \mu^+ \,\, \mu^- \,\, \text{or } q \, \overline{q} \,\, e^+ \,\, e^- \\ \text{signature, to derive 95% CL limits on } h_1^V. \,\, \text{Each limit is derived with other parameters} \\ \text{set to zero. They report: } -0.23 < h_1^Z < 0.23, \,\, -0.30 < h_3^Z < 0.16, \,\, -0.14 < h_1^{\gamma} < 0.14, \,\, -0.049 < h_3^{\gamma} < 0.044. \end{array}$

232 ACHARD 04H select 3515 $e^+e^- o Z\gamma$ events with $Z o q\overline{q}$ or $\nu\overline{\nu}$ at $\sqrt{s}=189$ –209 GeV to derive 95% CL limits on h_V^V . For deriving each limit the other parameters are fixed at zero. They report: $-0.153 < h_I^Z < 0.141, -0.087 < h_Z^Z < 0.079, -0.220 <$

 $h_3^Z < 0.112, \, -0.068 < h_4^Z < 0.148, \, -0.057 < h_1^{\gamma} < 0.057, \, -0.050 < h_2^{\gamma} < 0.023,$ $-0.059 < h_3^{\gamma} < 0.004, -0.004 < h_4^{\gamma} < 0.042.$

233 ABBIENDI,G 00c study $e^+e^- \rightarrow Z\gamma$ events (with $Z \rightarrow q\overline{q}$ and $Z \rightarrow \nu \overline{\nu}$) at 189 GeV to obtain the central values (and 95% CL limits) of these couplings: $h_1^Z = 0.000 \pm 0.100 \; (-0.190, 0.190), \; h_2^Z = 0.000 \pm 0.068 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.068 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.008 \; (-0.128, 0.128), \; h_3^Z = 0.000 \; \pm 0.000 \; \pm 0.000 \; \pm 0.000 \; + 0.000 \; + 0.000 \; + 0.000 \; + 0.000 \;$ $-0.074^{+0.102}_{-0.103}$ (-0.269, 0.119), $h_4^Z = 0.046 \pm 0.068$ (-0.084, 0.175), $h_1^{\gamma} = 0.000 \pm 0.008$ 0.061 (-0.115, 0.115), $h_2^{\gamma} = 0.000 \pm 0.041$ (-0.077, 0.077), $h_3^{\gamma} = -0.080 + 0.039 - 0.041$ $(-0.164, -0.006), \ h_4^{\gamma} = 0.064 + 0.033 \\ -0.030 \ (+0.007, +0.134). \ \ \text{The results are derived}$ assuming that only one coupling at a time is different from zero.

²³⁴ ABBOTT 98M study $p\overline{p} \rightarrow Z\gamma + X$, with $Z \rightarrow e^+e^-, \, \mu^+\mu^-, \, \overline{\nu}\nu$ at 1.8 TeV, to obtain 95% CL limits at $\Lambda=$ 750 GeV: $|h_{30}^Z|<$ 0.36, $|h_{40}^Z|<$ 0.05 (keeping $h_i^{\gamma}=$ 0), and $|h_{30}^{\gamma}|<0.37, |h_{40}^{\gamma}|<0.05 \text{ (keeping } h_{i}^{\gamma}=0), \text{ and } |h_{30}^{\gamma}|<0.37, |h_{40}^{\gamma}|<0.05 \text{ (keeping } h_{i}^{\gamma}=0). \text{ Limits on the } \textit{CP-violating couplings are } |h_{10}^{\gamma}|<0.36, |h_{20}^{\gamma}|<0.05 \text{ (keeping } h_{i}^{\gamma}=0), \text{ and } |h_{10}^{\gamma}|<0.37, |h_{20}^{\gamma}|<0.05 \text{ (keeping } h_{i}^{\gamma}=0).}$

²³⁵ ABREU 98K determine a 95% CL upper limit on $\sigma(e^+\,e^-\,
ightarrow\,\gamma\,+$ invisible particles) <2.5 pb using 161 and 172 GeV data. This is used to set 95 % CL limits on $|h_{30}^{\gamma}| <$ 0.8 and $|h_{30}^{Z}|<1.3$, derived at a scale $\Lambda=1\,{
m TeV}$ and with n=3 in the form factor representation.

Combining the LEP results properly taking into account the correlations the following 95 % CL limits are derived (CERN-PH-EP/2005-051 or hep-ex/0511027)

$$-0.30 < f_4^Z < +0.30,$$
 $-0.34 < f_5^Z < +0.38,$ $-0.17 < f_4^{\gamma} < +0.19,$ $-0.32 < f_5^{\gamma} < +0.36.$

²³⁶ Using data collected in the center of mass energy range 192–209 GeV, SCHAEL 09 select 318 $e^+\,e^ightarrow~$ $Z\,Z$ events with 319.4 expected from the standard model. Using this data they derive the following 95% CL limits: $-0.321 < f_A^{\gamma} < 0.318$, $-0.534 < f_A^{Z} < 0.534$ $0.534,\, -0.724 < f_{\bf 5}^{\gamma} < 0.733,\, -1.194 < f_{\bf 5}^{Z} < 1.190.$

237 ABAZOV 08k search for ZZ and $Z\gamma^*$ events with $1\,{\rm fb}^{-1}$ $p\overline{p}$ data at $\sqrt{s}=1.96$ TeV in (e e) (e e), $(\mu\mu)(\mu\mu)$, (e e) $(\mu\mu)$ final states requiring the lepton pair masses to be > 30 GeV. They observe 1 event, which is consistent with an expected signal of 1.71 ± 0.15 events and a background of 0.13 ± 0.03 events. From this they derive the following limits, for a form factor (A) value of 1.2 TeV: $-0.28 < f_{40}^Z < 0.28$, $-0.31 < f_{50}^Z < 0.28$ $0.29, \, -0.26 < f_{40}^{\gamma} < 0.26, \, -0.30 < f_{50}^{\gamma} < 0.28.$

 238 Using data collected at $\sqrt{s}=$ 183–208 GeV, ABDALLAH 07c select 171 $e^+\,e^-\to~$ Z Z events with $Z
ightarrow~q\,\overline{q}$ or lepton pair (except an explicit au pair), and 74 e^+e^- – events with a $q\overline{q}\,\mu^+\,\mu^-$ or $q\overline{q}\,e^+\,e^-$ signature, to derive 95% CL limits on f_i^V . Each limit is derived with other parameters set to zero. They report: $-0.40 < f_A^{Z'} < 0.42$, $-0.38 < f_5^Z < 0.62, \, -0.23 < f_4^{\gamma} < 0.25, \, -0.52 < f_5^{\gamma} < 0.48.$

239 ABBIENDI 04c study ZZ production in e⁺e⁻ collisions in the C.M. energy range 190–209 GeV. They select 340 events with an expected background of 180 events. Including the ABBIENDI 00N data at 183 and 189 GeV (118 events with an expected background of 65 events) they report the following 95% CL limits: $-0.45 < f_4^{Z} < 0.58$, $-0.94 < f_5^{Z} < 0.25$, $-0.32 < f_4^{\gamma} < 0.33$, and $-0.71 < f_5^{\gamma} < 0.59$.

 240 ACHARD 03p study Z-boson pair production in e^+e^- collisions in the C.M. energy range 200–209 GeV. They select 549 events with an expected background of 432 events. Including the ACCIARRI 996 and ACCIARRI 990 data (183 and 189 GeV respectively, 286 events with an expected background of 241 events) and the 192–202 GeV ACCIARRI 011 results (656 events, expected background of 512 events), they report the following 95% CL limits: $-0.48 \le f_4^Z \le 0.46, -0.36 \le f_5^Z \le 1.03, -0.28 \le f_4^{\gamma} \le 0.28, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.28, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.28, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48, \text{ and } -0.40 \le 0.48 \le f_4^{\gamma} \le 0.48 \le$ $f_5^{\gamma} \leq 0.47$

ANOMALOUS W/Z QUARTIC COUPLINGS

Revised March 2012 by M.W. Grünewald (U. Ghent) and A. Gurtu (King Abdulaziz University).

The Standard Model quartic couplings, WWZZ, $WWZ\gamma$, $WW\gamma\gamma$, and $ZZ\gamma\gamma$ lead to negligible effects at LEP energies, while they are important at a TeV Linear Collider. Outside the Standard Model framework, possible quartic couplings, a_0, a_c, a_n , are expressed in terms of the following dimension-6 operators [1,2];

$$\begin{split} L_6^0 &= -\frac{e^2}{16\Lambda^2} \; a_0 \; F^{\mu\nu} \; F_{\mu\nu} \vec{W^{\alpha}} \cdot \vec{W_{\alpha}} \\ L_6^c &= -\frac{e^2}{16\Lambda^2} \; a_c \; F^{\mu\alpha} \; F_{\mu\beta} \vec{W^{\beta}} \cdot \vec{W_{\alpha}} \end{split}$$

$$\begin{split} L_6^n &= -i\frac{e^2}{16\Lambda^2} \; a_n \epsilon_{ijk} \; W_{\mu\alpha}^{(i)} \; W_{\nu}^{(j)} \; W^{(k)\alpha} F^{\mu\nu} \\ \widetilde{L}_6^0 &= -\frac{e^2}{16\Lambda^2} \; \widetilde{a}_0 \; F^{\mu\nu} \; \widetilde{F}_{\mu\nu} \vec{W}^\alpha \cdot \vec{W}_\alpha \\ \widetilde{L}_6^n &= -i\frac{e^2}{16\Lambda^2} \; \widetilde{a}_n \epsilon_{ijk} \; W_{\mu\alpha}^{(i)} \; W_{\nu}^{(j)} \; W^{(k)\alpha} \widetilde{F}^{\mu\nu} \end{split}$$

where F,W are photon and W fields, L_6^0 and L_6^c conserve C, P separately (\widetilde{L}_6^0 conserves only C) and generate anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ couplings, L_6^n violates CP (\widetilde{L}_6^n violates both C and P) and generates an anomalous $W^+W^-Z\gamma$ coupling, and Λ is an energy scale for new physics. For the $ZZ\gamma\gamma$ coupling the CP-violating term represented by L_6^n does not contribute. These couplings are assumed to be real and to vanish at tree level in the Standard Model.

Within the same framework as above, a more recent description of the quartic couplings [3] treats the anomalous parts of the $WW\gamma\gamma$ and $ZZ\gamma\gamma$ couplings separately leading to two sets parameterized as a_0^V/Λ^2 and a_c^V/Λ^2 , where V=W or Z.

At LEP the processes studied in search of these quartic couplings are $e^+e^- \to WW\gamma$, $e^+e^- \to \gamma\gamma\nu\overline{\nu}$, and $e^+e^- \to$ $Z\gamma\gamma$ and limits are set on the quantities a_0^W/Λ^2 , a_c^W/Λ^2 , a_n/Λ^2 . The characteristics of the first process depend on all the three couplings whereas those of the latter two depend only on the two CP-conserving couplings. The sensitive measured variables are the cross sections for these processes as well as the energy and angular distributions of the photon and recoil mass to the photon pair.

Combining published and unpublished preliminary LEP results the following 95% CL intervals for the QGCs associated with the $ZZ\gamma\gamma$ vertex are derived (CERN-PH-EP /2005-051 or hep-ex /0511027):

$$\begin{array}{l} -0.008 < a_0^Z/\Lambda^2 < +0.021 \\ -0.029 < a_c^Z/\Lambda^2 < +0.039 \end{array}$$

• • We do not use the following data for averages, fits, limits, etc. • • 241 ABBIENDI ²⁴² HEISTER 04A ALEF ²⁴³ ACHARD 02G L3

²⁴¹ ABBIENDI 04L select 20 $e^+\,e^-
ightarrow \,
u \overline{
u} \gamma \gamma$ acoplanar events in the energy range 180–209 GeV and 176 $e^+\,e^ightarrow\,q\,\overline{q}\,\gamma\gamma$ events in the energy range 130–209 GeV. These samples are used to constrain possible anomalous $W^+W^-\gamma\gamma$ and $ZZ\gamma\gamma$ quartic couplings. Further combining with the $W^+W^-\gamma$ sample of ABBIENDI 04B the following one-parameter 95% CL limits are obtained: $-0.007 < a_0^Z/\Lambda^2 < 0.023 \ {\rm GeV}^{-2}, -0.029 < a_0^Z/\Lambda^2 < 0.020 \ {\rm GeV}^{-2}, -0.052 < 0.020 \ {\rm GeV}^{-2}, -0.$

0.037 GeV $^{-2}$. 242 In the CM energy range 183 to 209 GeV HEISTER 04A select 30 $e^+e^- o \nu \overline{\nu} \gamma \gamma$ events with two acoplanar, high energy and high transverse momentum photons. The photon-photon acoplanarity is required to be > 5°, $E_{\gamma}/\sqrt{s}>0.025$ (the more energetic photon having energy > 0.2 \sqrt{s}), p $_{T_{\gamma}}/{\rm E_{beam}}~>$ 0.05 and $|\cos\theta_{\gamma}|~<$ 0.94. A likelihood fit to the photon energy and recoil missing mass yields the following one-parameter 95% CL limits: $-0.012 < a_C^2/\Lambda^2 < 0.019~{\rm GeV}^{-2}, -0.041 < a_C^2/\Lambda^2 < 0.044~{\rm GeV}^{-2}$, $-0.060 < a_0^W/\Lambda^2 < 0.055 \text{ GeV}^{-2}, -0.099 < a_C^W/\Lambda^2 < 0.093 \text{ GeV}^{-2}.$

²⁴³ ACHARD 026 study $e^+e^- \rightarrow Z\gamma\gamma \rightarrow q\overline{q}\gamma\gamma$ events using data at center-of-mass energies from 200 to 209 GeV. The photons are required to be isolated, each with energy

>5 GeV and $|\cos\theta|<0.97$, and the di-jet invariant mass to be compatible with that of the Z boson (74–111 GeV). Cuts on Z velocity ($\beta<0.73$) and on the energy of the most energetic photon reduce the backgrounds due to non-resonant production of the $q\overline{q}\gamma\gamma$ state and due to ISR respectively, yielding a total of 40 candidate events of which 8.6 are expected to be due to background. The energy spectra of the least energetic photon are fitted for all ten center-of-mass energy values from 130 GeV to 209 GeV (as obtained adding to the present analysis 130–202 GeV data of ACCIARRI 01E, for a total of 137 events with an expected background of 34.1 events) to obtain the fitted values $a_0/\Lambda^2=0.00+0.02$ GeV-2 and $a_c/\Lambda^2=0.03+0.02$ GeV-2, where the other parameter is kept fixed to its Standard Model value (0). A simultaneous fit to both parameters yields the 95% CL limits -0.02 GeV $-2< a_o/\Lambda^2<0.03$ GeV-2 and -0.07 GeV $-2< a_o/\Lambda^2<0.05$ GeV-2<0.05 GeV-2<0 ${\rm GeV}^{-\,2} < \! a_{C}/\Lambda^{2} < 0.05~{\rm GeV}^{-\,2}.$
