Abstract

This paper explores new motivations behind giving. Specifically, it focuses on personal involvement and responsibility to explain why decision makers give positive amounts in dictatorial decisions. The experiment is designed to uncover these motivations. Subjects face the problem of a dictator's allocation of an indivisible pie P to one of two players; indivisibility creates an extremely unequal outcome and the dictator is given a chance to correct this outcome at a cost. The willingness to pay to correct the outcome is examined under different scenarios so that we learn about several features concerning preferences.

Keywords: Fairness, Dictator game, Moral cost.

JEL Class.: C91, D63, D64.

1 Motivation

Recent experimental literature has interpreted giving in dictator game (DG hereafter) in terms of fairness-based preferences (see Camerer, 2003, chap. 2). Nevertheless, experimental studies such as Hoffman *et al.* [17] & [18], Dana *et al.* [10] & [11], Lazear *et al.* [19] have questioned this interpretation. According to these studies some dictators do not share their endowments just because their preferences are other-regarding. Giving in DG could be influenced by self-centered reasons. For instance, by social reputation, by the level of “transparency” of the mapping between dictators’ decisions and outcomes, or as a result of feeling “guilt” or “shame” for not giving.

This paper aims to provide a better understanding of self-regarding motives behind giving in DG. Our hypothesis is that selfish allocations in DG may have a *moral cost* attached for decision makers. Under fairness concerns, this moral cost is to be understood as emerging from agents feeling uncomfortable with (too) unequal results. However, the moral cost attached to a dictator’s selfish decision may be related not only to the nature of the result, but to the very action of making the decision. In other words, pangs of conscience do not only arise from the fact that dictators’ selfish decisions bring about an unequal distribution of payoffs; they may be largely the result of dictators being *responsible for* and *beneficiaries of* unfair decisions.

There might be a restriction of self-interest in dictatorial allocations that is context-driven rather than arising from a desire for a fair outcome.¹ In this regard, our main hypothesis is the following:

For a given unfair payoff distribution, giving decreases when the moral cost attached to decisions is reduced.

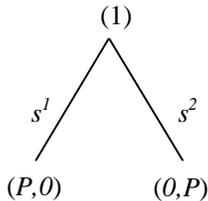

To analyze this hypothesis, we have designed an experiment in which a decision maker faces the problem of allocating an indivisible pie P to one of two players. Indivisibility creates an extremely unequal outcome. Then, taking this unequal outcome as a starting point, the agent is given the chance to correct the distribution at a cost. The willingness to incur this cost is examined under a series of scenarios differing in the moral costs attached to decision-making.

The benchmark allocation problem is an all-or-nothing dictator game

¹That human beings care not only about outcomes but also about the process leading to those outcomes is well documented; see Gintis *et al.* [16] and Aguiar & Brañas-Garza [1].

(DG^{an} hereafter). In a standard DG, the task of subject i is to allocate a “pie”, P , between a recipient j and himself/herself; that is, he/she has to decide his/her payoff, π_i , and, thus, his/her recipient’s, $\pi_j = P - \pi_i$. We modify this standard version of the dictator game by making P indivisible (see a similar approach in Bolton *et al.* [4] and Brañas-Garza [6]²). Thus, as Figure 1 shows, the subjects’ Decision 1 in the DG^{an} is reduced to just two possible allocations: $(\pi_i, \pi_j) = (P, 0)$ if i chooses strategy s^1 , and $(\pi_i, \pi_j) = (0, P)$ if he/she opts for s^2 .

Figure 1: THE ALL-OR-NOTHING
DICTATOR GAME (DG^{an}): DECISION 1

Subjects are therefore confronted with the dilemma of either keeping the whole pie for themselves or adopting a purely altruistic behavior in which the recipient receives the entire pie; this design enlarges the moral dimension of the decision problem.

Following the standard selfish behavior assumption, let us suppose that subjects choose strategy s^1 , giving rise to an unequal payoff distribution in which they keep the whole pie for themselves. Dictators are then given the opportunity to amend the distribution resulting from their decision. In particular, using part of the pie they got in Decision 1 of this DG^{an} , they are given the chance to pay something in order to give a new, whole pie to their recipient. That is, instead of having subjects face a direct trade-off between their own payoffs and those of the partner, as it is usually done in the literature on dictator’s choices, we elicit the willingness to pay of individual i (wtp_i , where $i = 1, \dots, n$, and n is the number of dictators) through a payment card. The use of a payment card in this context is particularly appropriate since it allows to measure the differences in wtp when the benefit to the recipient is constant and independent of dictator’s sacrifice.

²In Bolton *et al.* [4], dictators always receive at least a fixed prize. In our design, as in Brañas-Garza [6], they have to decide whether they get the whole pie or nothing.

If the average willingness to pay is positive, $\widehat{WTP} = \frac{1}{n} \sum_i wtp_i > 0$, this would mean that agents, on average, are ready to sacrifice part of their own payoff to improve recipients' welfare. Note in this regard that if subject i reveals a positive willingness to pay ($wtp_i > 0$), then, $\pi_i < \pi_j$. The reason is that i would be sacrificing part of P to give a new, whole pie to j ; that is, the payoff distribution would become $(\pi_i, \pi_j) = (P - wtp_i, P)$ instead of $(\pi_i, \pi_j) = (P, 0)$. In other words, agents would have accepted a disadvantageous type of inequity to mitigate the extreme advantageous inequity that resulted from choosing s^1 in Decision 1.

Our experiment, as discussed below, produces the result that the average willingness to pay in the DG^{an} is positive. Among the different explanations economic theory provides for this result, three are particularly relevant.³

1st explanation: Inequity aversion (ia)

Definition 1 (ia) *Individuals are inequity averse when “they are willing to give up some material payoff to move in the direction of more equitable outcomes” (Fehr & Schmidt, 1999, p. 819).*

With this definition at hand, the observed $\widehat{WTP} > 0$ may be explained as the result of subjects' attempts to reduce the (advantageous) extreme inequity generated as a result of choosing s^1 in Decision 1.

Nevertheless, note that $wtp_i > 0$ also means that subject i is ready to accept a disadvantageous inequity.

2nd explanation: Efficiency gains (eg)

Definition 2 (eg) *Subjects are efficiency seekers if they care about the sum of individual payoffs.*

In line with this definition, efficiency gains are a possible explanation for $\widehat{WTP} > 0$, because the correction of the initial decision in the DG^{an} involves an increase in the sum of payoffs.⁴ That is, for subject i^{th} , $[(P - wtp_i) + P] > [P + 0]$.

³Besides these three explanations, theoretical models sometimes include reciprocity as an explanation for cooperative behavior (see Charness & Rabin [9]). For instance, in repeated games, the fear of punishment induce subjects to be kind. In the problem stated in Figure 1 there is clearly no room for reciprocity.

⁴In the standard DG there are no efficiency gains, although they can be found in modified versions of the game as in Dana *et al.* [11] or Andreoni & Vesterlund [2].

3rd explanation: Social game attributes

Andreoni & Miller [3] emphasize the context of the game. In particular, they define a vector γ of attributes of a game, which would include aspects such as social variables, the rules of the game or its framing.

In terms of subject i 's utility function, this view implies that agent i faces a utility function as follows:

$$u_i(x, \gamma),$$

where $x = (x_i, x_j)$ is a feasible allocation of resources (the sum of payoffs is equal to or lower than the total amount available, $x_i + x_j \leq X$) and γ is a vector of attributes describing the relevant features of the process generating the allocation. That is, subjects may care not only about the final consequences of their decisions but also about other aspects such as the means of achieving the final outcome.

In this paper we consider two dimensions of γ . Both are related to the possibility of Decision 1 having some *moral cost* attached to it.

The first dimension of γ we consider is γ_1 , personal involvement in allocations.

Definition 3 (γ_1) *A subject has personal involvement in an allocation, γ_1 , when he/she obtains advantage directly and personally from the payoff distribution.*

Subjects may incur a γ_1 -type moral cost when they have to decide on an allocation where all their earnings are recipients' losses. A standard example of this type of decision is DG, where each unit of the pie the dictator keeps for himself/herself is at the expense of the other player.

If individuals do not like to adopt Decision 1 shown in Figure 1 because they benefit directly from it at the expense of the recipient's payoff, then a positive \widehat{WTP} could be explained in terms of the moral attribute of the game γ_1 .

The second relevant dimension of γ is subjects' personal responsibility for decisions, γ_2 .

Definition 4 (γ_2) *Subjects are responsible for a decision when they have control over the results of the decision.*

If subjects feel responsible for making a decision, they incur the cost (or have the benefit) attached to being directly responsible for the results of that decision. Note that the nature of the effect depends on whether it is a *pleasant* or *unpleasant* decision.

In the case of the DG^{an} , γ_2 may adopt the particular form of subjects feeling responsible for an extremely unequal outcome. As a result, when they are offered the opportunity to remedy this situation, they agree to pay to modify the distribution.

In the light of these definitions, our previous hypothesis can now be formulated as follows:

Hypothesis All-or-nothing dictatorial-type decisions are affected by the attributes of the game. In particular, for a given unfair distribution of payoffs, when the presence of γ_1 and γ_2 is reduced or canceled, giving decreases.

Note that γ_1 and γ_2 make reference to the “moral dimension” of decisions; that is, to their “right” or “wrong” nature. However, these two variables are not only related to the moral nature of the outcome but also to the characteristics of the very action of making decisions. Accordingly, this moral dimension refers not only to one’s decisions being detrimental to others; i.e., it is not only other-regarding but also self-centered. This implies that, if the hypothesis above is correct, a decision which is equally detrimental to others may have attached to it a lower moral cost for the decision maker when he/she does not feel guilty for his/her role in the decision-making process. In our setup, there are guilt feelings when the decision maker benefits from the decision and/or feels responsible for the decision.

When γ_1 and γ_2 do not play a role, agents’ willingness to pay to balance the distribution is explained in terms of inequity aversion and efficiency gains. If the hypothesis is true then giving will increase when these two self-centered motivations are present.

The following section describes the different treatments used to analyze this hypothesis and the conditions in which the experiments were conducted.

2 Experimental design and procedures

We ran four treatments to explore this conjecture. Table 1 provides a summary of the first three. Treatment 4 will be discussed in Section 5.

All-or-Nothing Dictator Game ($T1$): This all-or-nothing dictator game (DG^{an} hereafter) is the control treatment. The decision task of decision makers in this treatment is to allocate an indivisible pie, P , of 10 experimental currency units (ECUs) as shown in Figure 1. Subjects act as dictators, and their recipients are students randomly chosen from the class list. Note that both strategies s^1 and s^2 in Decision 1 give rise to extreme distributions because the 10 ECU pie is not divisible; that is, agents can only generate an extremely unequal payoff distribution. After this inequity is created, they are given the opportunity without previous announcement to balance the payoff distribution by incurring a cost to give a new, whole pie to their recipient. To elicit subjects' willingness to pay, a standard payment card is used.

The payment card gives subjects the chance to pay part of their endowment to give a whole, new 10 ECU pie to the recipient. That is, if agents choose s^1 in Decision 1, as may be expected, this payment card gives them the opportunity to nearly balance the distribution of final payoffs (see Appendix 1 for the instructions concerning the payment cards in $T1$, $T2$ and $T3$). As far as we know the joint use of dictator choices and payment cards is new in this literature. In other experiments players have to decide directly the amount to give (if any), so that subjects face a trade-off between their own payoffs and the partner's. Our procedure is quite similar but here subjects have the chance to give a new whole pie to the rival. As in the standard game this pie is costly.⁵

Table 1: TREATMENTS AND DECISION 1

		RECIPIENT 1	RECIPIENT 2	FEASIBLE PAYOFFS		
DG^{an}	$T1$	dictator	classmate	(10, 0)	(0, 10)	
AD^{an}	$T2$	classmate	classmate	(10, 0)	(0, 10)	
AD_{random}	$T3$	classmate	classmate	(10, 0)	(0, 10)	<i>Random</i>

All-or-Nothing Allocation Decision ($T2$): In this scenario, subjects have to assign a 10 ECU indivisible pie in Decision 1; but they do not directly

⁵Usually, the transfer price is the unit. However, some papers have used several prices (Andreoni & Vesterlund [2]) or prices that encourage altruistic behavior (Dana *et al.* [11]).

benefit from this all-or-nothing allocation decision (AD^{an} hereafter). The task is to allocate the indivisible pie between two classmates and no matter the distribution the decision maker earns a 10 ECU show-up fee.⁶ This show-up fee will be used to make subjects reveal their willingness to pay to give a new, whole 10 ECU pie to the recipient who got a zero payoff in Decision 1. Note that the only difference between $T1$ and $T2$ is the decision maker's personal involvement in the payoffs of an unequal allocation decision; that is, γ_1 influences subjects' decision making in $T1$, but it does not do so in $T2$.

All-or-Nothing Allocation Decision with Random Lever ($T3$): This all-or-nothing allocation decision with random lever (AD_{random} hereafter) is identical to $T2$, except that subjects have three options in Decision 1: s^1 , s^2 and what we call "Random Lever". Choosing the latter option implies that agents delegate their decision to a lever which selects strategies s^1 and s^2 randomly. Thus, those subjects who choose the random lever might feel they withdraw control over the payoff distribution. If this were the case, γ_2 would not influence their decision; that is, even if recipients are chosen randomly from the class list, the decision makers' feeling of responsibility for the resulting unequal distribution may be reduced.

Experimental sessions were conducted among Economics students taking Microeconomics 1 (four sections) at the University of Granada (Spain). This course is taught during the spring semester of the first year. The total sample comprises 112 + 117 subjects divided into four treatments (the distribution of subjects by treatments was: $T1$: 29, $T2$: 36, $T3$: 23, and $T4$: 24). The other 117 subjects correspond to variations of the treatments: $T1'$: 24, $T2'$: 22, 23, $T3'$: 24, and $T4'$: 24.

Subjects faced the allocation decisions described in Table 1, named *Decision 1*. Dictators were informed that recipients would be chosen randomly from the class list. There were four sessions (one for each section of the course), and all treatments and variations were conducted the same day in March 2005. In each of these four sessions at least two treatments were conducted, but each subject played only one treatment, i.e. each subject faced

⁶This AD^{an} is reminiscent of Solomon's dilemma (see Ponti [20] and Ponti *et al.* [21]) in the sense that our dictators face a similar decision to that of King Solomon's.

just one allocation decision. No subject had any information regarding the game other subjects were playing.

After facing Decision 1, subjects were asked how much they would pay to give a new, whole pie to the recipient who did not get anything. They did not know in advance they would face this second decision. To elicit the wtp_i of agent i we used a standard payment card⁷ whose instructions are shown in Appendix 1.

The payoff rules adopted aimed at creating a very competitive context. In this sense, subjects were informed that the number of points obtained during the experimental session (jointly with the points in other four experimental sessions in which they would participate during the course⁸) would modify the final grade of the course in the following way. Each of the 4 sections of the course plays a different tournament. The winner in each class receives three points (out of ten) to be added to the final grade. Other subjects' grades depend on how close their performance is to the winner's.

Note that paying with grade points instead of money implies that there is no possibility of ex post exchange and provides strong enough incentives for students.

After running the experiment, we asked subjects about their motivations. The aim was to compare subjects' opinions to our conjectures that their decisions would be driven by personal involvement and responsibility. We asked 21 subjects (a complete section of the course) out of the whole sample to fill a questionnaire. The questionnaire was given a week after the experiment was conducted; at that point, we had not yet provided any information to any of the participants about the objectives of the experiment or about preliminary results. The questionnaire consisted of three parts, as discussed below.

3 The role of γ_1 in giving

Now we explore how inequity aversion (*ia*), efficiency gains (*eg*), personal involvement in allocations (γ_1) and responsibility for the decision (γ_2) affect individual decisions in treatments $T1$, $T2$ and $T3$. Note that our analysis of the effect of these variables is between subjects. Table 2 summarizes the

⁷To induce subjects to reveal their true willingness to pay, they were informed that only one randomly chosen row would be effective.

⁸The sequence was as follows: a dictator game (March), GRE maths test (beginning of April), risk aversion tests (end of April), and travelers' dilemma (June).

relevant features for each treatment.

Table 2: TREATMENT SUMMARY

Treatments		Variables			
$T1$	DG^{an}	ia	eg	γ_1	γ_2
$T2$	AD^{an}	ia	eg		γ_2
$T3$	AD_{random}^*	ia	eg		

*Only for individuals who made use of the random lever.

Table 3 presents the relevant results for $T1$, $T2$ and $T3$. Recall that we use the DG^{an} as a control treatment. Row 1 in Table 3 refers to subjects who play strategy s^1 in this treatment.⁹ Specifically, it shows the mean and the frequency distribution of these subjects' willingness to pay to give a new 10 ECU pie to their respective recipients. On average, decision makers are willing to pay 2.69. In addition, 82% of individuals are willing to pay a positive amount of ECUs to modify the extremely unequal payoff distribution resulting from s^1 .

Result 1: After facing Decision 1 in the DG^{an} , 82% of subjects show a positive willingness to pay to balance the distribution. In this treatment, $\widehat{WTP} > 0$ is the result of the joint effect of ia , eg , γ_1 and γ_2 .

The relative importance of each of these four variables cannot be assessed in the DG^{an} . The AD^{an} and the AD_{random} are designed to uncover the effect of γ_1 and γ_2 .

Table 3: MAIN RESULTS IN T1, T2 & T3

		Frequency							
	n	Mean	0	1	2	3	4	5+	
DG^{an}	$T1$	27	2.69	5(18%)	2(7%)	4(14%)	5(18%)	7(25%)	4(14%)
AD^{an}	$T2$	36	1.72	13(36%)	4(11%)	6(16%)	6(16%)	7(19%)	0(0%)
AD_{rand}	$T3$	11	0.73	5(45%)	5(45%)	0(0%)	1(9%)	0(0%)	0(0%)
AD_{Nrand}	$T3$	12	1.58	4(33%)	2(17%)	3(25%)	1(8%)	2(17%)	0(0%)

⁹2 subjects out of 29 chose s^2 in the DG^{an} .

First, we compare DG^{an} data with data from AD^{an} . The difference between the tasks in these two treatments is that decision makers do not benefit directly from their decisions in the latter and therefore γ_1 could not possibly influence them. In this regard, individuals' willingness to pay decreases to 1.72 on average when γ_1 is not present, i.e. when the decision maker is not involved in the payoff allocations.

Moreover, the percentage of subjects who are not ready to pay anything to reverse the results obtained from s^1 in the AD^{an} doubles the percentage observed in DG^{an} (36% vs. 18%). That is, the percentage of people willing to pay a positive amount falls to 64%.

Another surprising result is that 14% of subjects in the DG^{an} are ready to pay half of the pie, whereas none of the participants in the AD^{an} reveals such a high willingness to pay. Using the Mann-Whitney test to compare the distributions of the two treatments ($Z = -1.92$; $p = 0.05$), the null is rejected; i.e., these distributions are not drawn from the same population.

Brañas-Garza *et al.* [7] (BDE hereafter) analyze the effect of friendship on dictatorial allocations. More precisely, BDE compares the DG^{an} where recipients are strangers to dictators (see row 1 of Table 3 for this treatment's results) with a DG^{an} where recipients are dictator's friends.¹⁰ Interestingly, there are no significant differences between them. In fact, the average *WTP* in both treatments (2.64 in the latter and 2.69 in the former) and their frequency distributions are similar.¹¹ These results provide evidence that friendship does not matter in giving but they also imply that our results are robust to variations.

With the same purpose, BDE also compares the AD^{an} where the recipients are strangers to the dictator (see row 2 of Table 3) with identical allocation decisions but where the dictator faces either a friend and a stranger or two friends. The second treatment has an average *WTP* equal to 1.55

¹⁰In those treatments where recipients are friends, instead of using the class list to randomly select the dictators' partners, recipients were randomly chosen from a list of friends he/she had revealed. The four treatments and their variations were conducted the same day and each subject participated only once either in one of the treatments or in a variation.

¹¹In a sample of 22 individuals, 2 of them gave 0 ECUs; 4 subjects, 1 ECU; 4 subjects, 2 ECUs; 5 subjects, 3 ECUs; 4 subjects, 4 ECUs; and 3 subjects, 5 ECUs or more (see BDE).

($n = 22$)¹² and the last one an average WTP of 2.04 ($n = 23$).¹³ Furthermore, the hypothesis of equal distributions for the three treatments cannot be rejected. In conclusion, the variations introduced in the treatments produced similar results to those presented in Table 3.

Hence, comparing the results of the DG^{an} and the AD^{an} we have:

Result 2: When γ_1 is removed, \widehat{WTP} decreases from 2.69 in the DG^{an} to 1.72 in the AD^{an} .

Therefore, we can conclude:

Result 3: There is a positive causal relationship between γ_1 and subjects' wtp .

Now, we explore subjects' opinion regarding γ_1 . We explained to the 21 participants in the questionnaire the basic features of a standard DG. In addition, we gave a brief introduction on how subjects' decisions in this type of game may conflict with the standard hypothesis of utility maximization. Then we described our experiment's benchmark –i.e. the DG^{an} – and reminded individuals how the payment card worked.

Finally, we told individuals that the average willingness to pay in the DG^{an} they had participated in was positive; in particular that $\widehat{WTP} = 2.69$. We added that *a priori* this could be due to four different variables and asked subjects to order them according to their capability to explain this positive sign of \widehat{WTP} .

The four variables we proposed and the way we defined them in the questionnaire were as follows:¹⁴

1. EFFICIENCY (*eg*): To make the sum of all players' payoffs as high as possible.
2. INEQUITY AVERSION (*ia*): A large difference between those who get the highest payoff and those who get the lowest is annoying.

¹²In a sample of 22 individuals, 7 of them gave 0 ECUs; 4 subjects, 1 ECU; 7 subjects, 2 ECUs; 1 subject, 3 ECUs; 2 subjects, 4 ECUs; and 1 subject, 5 ECUs or more (see BDE).

¹³In a sample of 23 individuals, 4 of them gave 0 ECUs; 4 subjects, 1 ECU; 4 subjects, 2 ECUs; 9 subjects, 3 ECUs; and 2 subjects, 4 ECUs (see BDE).

¹⁴The four variables are shown in the same order in which they appeared on the test sheet.

3. CONSCIENCE (γ_1): To gain something, someone else has to lose; that is, I benefit from someone else’s loss.
4. HARD DECISION (hd): Decisions to be made are of the all-or-nothing type; that is, I cannot choose intermediate distributions.

Note that the “conscience” variable corresponds to γ_1 ; i.e., whether decision makers modify their wtp as a result of their personal involvement. The “hard decision” variable is just the main difference between standard DGs and our DG^{an} . The remaining two variables (“efficiency” and “inequity aversion”) are as defined above (see section 1).

Table 4 shows the main results regarding subjects’ ranking.

Table 4: SUBJECTS’ RANKING OF GIVING MOTIVATIONS IN DG^{an}

Ranking 1 st		Ranking 2 nd		Ranking 3 rd		Ranking 4 th	
	Frequency		Frequency		Frequency		Frequency
γ_1	12(57%)	ia	10(48%)	eg	10(48%)	hd	7(33%)
hd	4(19%)	hd	5(24%)	hd	5(24%)	eg	6(29%)
ia	3(14%)	γ_1	3(14%)	ia	4(19%)	γ_1	4(19%)
eg	2(10%)	eg	3(14%)	γ_1	2(9%)	ia	4(19%)

According to this Table, 12 subjects (i.e., 57% of the 21 participants in the questionnaire) considered “conscience” as the main motivation behind $\widehat{WTP} > 0$. Hence, subjects’ ranking provides some support for Result 3: self-regarding moral costs –specifically, γ_1 – play a role in dictatorial decisions.

Although we will return to this below, note also that subjects’ ranking suggests that inequity aversion and efficiency gains do not seem to be as important as γ_1 . The role of the “hard decision” variable in subjects’ motivation is not as clear: 9 subjects ranked it first or second and 12 subjects ranked it third or fourth.¹⁵

¹⁵To check the relative importance of eg , ia , γ_1 and hd in the opinion of the participants in the questionnaire, assume that being ranked 1st is valued at 4 points; being ranked 2nd, at 3 points; being ranked 3rd, at 2 points; and being ranked 4th, at 1 point. The score, then, would be as follows: γ_1 gets 65 points; ia , 54 points; hd , 48 points; and eg , 43 points. That is, according to subjects’ opinion, γ_1 is the most important variable to

4 The role of γ_2 in giving

Table 3 shows that when γ_1 is removed, \widehat{WTP} is still positive in the AD^{an} . Hence, personal involvement, γ_1 , is relevant, but it cannot entirely explain the level of \widehat{WTP} in all-or-nothing allocation tasks.

Let us turn our attention to γ_2 . To check whether feeling responsible for an unkind decision has any influence on wtp we designed $T3$ such that subjects face the same decision as in the AD^{an} , but they have the chance to avoid the allocation decision through a random device. Opting for this device is like “tossing a coin” to solve King Solomon’s dilemma and “the coin” is who decides how to allocate the pie. In $T3$, Decision 1 does not affect decision makers’ payoffs (i.e. γ_1 is absent) and our conjecture is that choosing the random option may help them mitigate their feeling of responsibility for the resulting allocation (i.e. for those subjects who choose the random lever, γ_2 has little or no influence).

In row 3 of Table 3, AD_{random} refers to those subjects who had the random device available in $T3$ and chose it. Almost half of the subjects (11 out of 23) opted for it. However, the other side of the coin is that 12 out of 23 subjects did not use it ($AD_{Nrandom}$ in row 4, Table 3). There are two opposing explanations for this choice. First, individuals who did not choose the random option do not care about the role of responsibility in their decision. Second, they do not feel that their responsibility could be removed by choosing the random lever.

Interestingly, the \widehat{WTP} in the $AD_{Nrandom}$ matches that obtained in the AD^{an} ($\widehat{WTP} = 1.72$ vs. 1.58). Furthermore, the Mann-Whitney test does not reject ($Z = -0.22$; $p = 0.82$) the hypothesis that data arising from the AD^{an} and the $AD_{Nrandom}$ are drawn from the same population. These statistical results seem to suggest that subjects who did not choose the random option when it was available perceived the problem they faced in the same way as those in the AD^{an} perceived theirs –where the allocation decision was the same, but the randomization device was absent. Therefore, these results provide some support for the second explanation above: decision makers in the $AD_{Nrandom}$ did not believe that choosing the randomization device would prevent them from feeling responsible for the unequal distribution.

explain $\widehat{WTP} = 2.69$ in our DG^{an} ; ia is the second most relevant variable; and hd and eg , with similar number of points, seem to be the least influential variables on individuals’ decisions.

By contrast, the Mann-Whitney test shows ($Z = -1.73$; $p = 0.08$) that data arising from the AD^{an} and the AD_{random} are not drawn from the same population. In addition, as Table 3 shows, the mean in the AD_{random} is one point lower than in the AD^{an} . In particular, \widehat{WTP} in the AD_{random} decreases to 0.73. In sum:

Result 4:

- (i) When the random option was available, 11 subjects out of 23 made use of it. For those subjects who did not use the random option $\widehat{WTP} = 1.58$, close to $\widehat{WTP} = 1.72$ in the AD^{an} . However, for the subjects who did use the random lever, $\widehat{WTP} = 0.73$, statistically different from $\widehat{WTP} = 1.72$ in the AD^{an} .
- (ii) For half the decision makers in $T3$ the random device did not remove subjects' responsibility. Consequently, the presence of random levers does not affect their wtp . However, for those subjects who chose the random device, γ_2 does play a role in all-or-nothing dictatorial decisions.

We reach the following conclusion:

Result 5: There is a positive causal relation between γ_2 and subjects' wtp .

We conducted variations of the allocation problem with random lever within the network of friends in BDE. Despite other differences, there are some interesting features: (i) The average WTP for the 10 subjects (out of 24) using the random lever ($\widehat{WTP} = 2.00$) is lower than for the 14 subjects not using it ($\widehat{WTP} = 2.29$); (ii) the Mann-Whitney test indicates that the difference in averages, 0.29, is not significant ($Z = -0.56$, $p = 0.58$). Along the lines of our Result 4 (ii), it seems that subjects facing distributional problems with friends did not see the advantage of using the random device.¹⁶

Concerning subjects' opinion about γ_2 , the main features of treatment $T3$ were briefly explained to the participants in the questionnaire given after

¹⁶Note in this respect that the list of friends is usually a short list, while strangers are selected from a large population. Thus, when facing friends dictators may have felt that the random lever mitigated but did not substantially reduce their level of responsibility.

conducting the experiment. We underlined that this treatment was an all-or-nothing allocation decision and, for the sake of clarity, we compared the random option to the chance to solve King Solomon’s dilemma by tossing a coin.

Next, we told the participants in the questionnaire that the average WTP was lower in the AD_{random} ($\widehat{WTP}_{AD_{random}} = 0.73$) than in the $AD_{Nrandom}$ and in the AD^{an} ($\widehat{WTP}_{AD_{Nrandom}} = 1.58$ and $\widehat{WTP}_{AD^{an}} = 1.72$). Then we asked subjects their opinion about the motivations for the \widehat{WTP} decrease when the random lever was chosen.

Nine subjects out of 21 (i.e. 43%) did not provide a clear conjecture for the decrease in \widehat{WTP} . Two of them pointed out that decision makers do not care about who receives the 10 ECU pie. One individual argued that choosing the random lever does not change the resulting payoff distribution: whether the random option is chosen or not, someone still loses.¹⁷

However, 12 subjects out of 21 (i.e. 57%) made explicit reference to *the lower level or lack of responsibility* in the resulting payoff distribution as the main cause for the reduction in \widehat{WTP} when the random option was chosen. This result is in line with our conjecture that giving is affected by γ_2 .

The conclusion of the above discussion is that the social attributes of games are relevant in dictatorial decisions (see Results 3 and 5). Specifically, in extremely unequal situations there seems to be a positive link between agents’ willingness to pay to reverse inequity and the self-regarding moral costs attached to being responsible for and benefitting from unfair decisions.

Indeed, after controlling for the effect of both γ_1 and γ_2 in all-or-nothing allocation decisions, the average willingness to pay to balance the outcome decreases. However, it still has a positive value in the AD_{random} ($\widehat{WTP} = 0.73$). In accordance with the description of treatments in Table 2, this positive value could be due to the joint effect of inequity aversion (*ia*) and efficiency gains (*eg*).

Going back to the questionnaire given to the experimental subjects, as Table 4 shows, only 3 participants in the questionnaire (i.e. 14% of the 21 subjects) ranked the capability of inequity aversion in first place to explain $\widehat{WTP} = 2.69$ in the DG^{an} . However, 13 subjects (62%) ranked this variable first or second. It could be stated, therefore, that the subjects’ opinion is not

¹⁷Six subjects provided “unclassifiable” answers. They made reference to reasons such as risk aversion, increase in the probability of being wrong, distrust in random choices, or being in equilibrium.

conclusive on the importance to be assigned to inequity aversion as regards decision makers' wtp to balance the payoff distribution in this treatment.

Concerning the influence efficiency gains may exert over \widehat{WTP} in DG^{an} , Table 4 shows that only 5 participants in the questionnaire (i.e. 24% of the 21 participants) ranked efficiency gains in first and second place when they were asked about the motivations for $\widehat{WTP} = 2.69$ in DG^{an} . This suggests that efficiency gains do not play a major role in subjects' wtp .¹⁸

To extend the analysis of how guilt feelings may influence decisions in the next section we explore a scenario where, after making Decision 1, subjects may avoid the resulting uneasiness by exiting the game.

5 Further evidence: Please, let me out!

This section presents the results of treatment $T4$. In this treatment, we elicit subjects' willingness to pay to avoid the discomfort of having to make Decision 1. Here, in contrast to treatments $T1$, $T2$ and $T3$ where subjects could balance the distribution, it is *Decision 1* itself that can be removed at a cost for the decision maker.¹⁹

All-or-Nothing Dictator Game with Exit Option ($T4$): Decision 1 is the same in this all-or-nothing dictator game with exit option (DG_{exit} hereafter) and in the DG^{an} . The difference between the two treatments is that in the DG_{exit} , after making Decision 1 and without previous announcement, subjects are offered the possibility of exiting the game.²⁰ Leaving the game renders Decision 1 invalid. Whether this exit option is free or not depends on agents' preferences. A payment card (see Appendix 2) is used to elicit their willingness to pay to cancel Decision 1 and exit the game.

Thus, the DG_{exit} analyzes how much agents are ready to pay in exchange for exiting the game and canceling their previous decision.

¹⁸Note that $\widehat{WTP} = 2.69$ in the DG^{an} is very similar to the results of other standard DGs where there are no efficiency gains. For instance, it is quite close to the 2.5 average giving of dictators in the standard single-room DG in Frohlich *et al.* [15]. Nevertheless, Fisman *et al.* [14] have shown that a majority of unselfish agents prefer to increase aggregate payoffs than to reduce differences in payoffs in a three-person DG.

¹⁹ $T4$ was conducted under the procedures described in Section 2 and in the same sessions as $T1$, $T2$ and $T3$.

²⁰For this type of approach, see Dana *et al.* [10] and Lazear *et al.* [19].

Table 5 shows \widehat{WTP} in $T1$, $T2$, $T3$ and $T4$,²¹ and whether or not the inequity aversion (ia), efficiency gains (eg), involvement in payments (γ_1) and responsibility for decisions (γ_2) variables are present in these four treatments. Subjects accept 8.91 on average to cancel Decision 1 and exit the game. In other words, the average amount of ECUs they are ready to give up to exit the game is $10 - 8.91 = 1.09$.

Table 5: TREATMENTS

					n	Mean
DG ^{an} ($T1$)	ia	eg	γ_1	γ_2	27	2.69
AD ^{an} ($T2$)	ia	eg		γ_2	36	1.72
AD _{random} ($T3$)	ia	eg			11	0.73
DG _{exit} ($T4$)	ia		γ_1	γ_2	22	1.09

As Table 5 shows, the variables which may influence the outcome in the DG_{exit} are inequity aversion (ia), dictators' personal involvement in payments (γ_1) and their responsibility for unkind decisions (γ_2). Note that there are no efficiency gains (eg) in this treatment. As a matter of fact, when $wtp_i > 0$ in the DG_{exit}, the payoff distribution becomes $(\pi_i, \pi_j) = (P - wtp_i, 0)$ instead of $(\pi_i, \pi_j) = (P, 0)$; that is, agent i suffers an individual loss for exiting the game which also involves an efficiency loss.

We have argued in this paper that what may sometimes appear as inequity aversion is in fact moral discomfort for having been involved in making a decision with unequal consequences or for having benefitted from it. The DG_{exit} provides additional support for this result. Assume that moral costs have no influence; then, $\widehat{WTP} = 1.09$ in the DG_{exit} would imply that the parameter which measures the utility loss from advantageous inequity in Fehr & Schmidt's [13] utility function is larger than 1 for some individuals. That is, if subject i 's wtp_i is positive, then, $\beta_i > 1$.²² Fehr & Schmidt [13] rejects this possibility: if $\beta_i = 1$,

²¹As in the DG^{an}, arguments focus on individuals who chose s^1 in Decision 1. Only 2 out of 24 subjects did not choose this strategy in the DG_{exit}.

²²Fehr & Schmidt's [13] utility function of inequity aversion is the following:

$$u_i(x) = x_i - \alpha_i \frac{1}{n-1} \sum_{j \neq i} \max\{x_j - x_i, 0\} - \beta_i \frac{1}{n-1} \sum_{j \neq i} \max\{x_i - x_j, 0\},$$

where $u_i(x)$ is the utility function of player i ; $x = x_1, \dots, x_n$ is the vector of monetary payoffs; n is the number of players; α_i is the sensitivity of individual i 's utility to dis-

... then player i is prepared to throw away one dollar in order to reduce his advantage relative to player j which seems very implausible. This is why we do not consider the case $\beta_i \geq 1$ (Fehr & Schmidt, 1999, p. 824).

Indeed, stating that our experimental subjects were ready to throw grade points away to reduce their advantageous position in the experiment's results does not seem to make too much sense. Given that $\beta_i > 1$ seems an implausible parameter value in terms of inequity aversion preferences, this variable by itself is not able to rationalize subjects' behavior in DG_{exit} .

Thus:

Result 6: In DG_{exit} , subjects are willing to give a positive payoff (1.09 on average) to avoid the moral costs (γ_1 and γ_2) attached to an allocation decision. Inequity aversion by itself cannot explain this behavior.

An interesting outcome of the DG_{exit} is that subjects are willing to give up some payoffs just to avoid being unkind.²³ This behavior could respond to what can be called the *ostrich's strategy*. When subjects face an unpleasant decision they may prefer "to hide their head in the sand" by canceling that decision even at a cost. Indeed, as Table 6 shows, 86% of the subjects chose to do so. More surprisingly, about half of them (54%) were ready to sacrifice

advantageous inequity; and β_i is the sensitivity of individual i 's utility to advantageous inequity. Since $\overline{WTP} = 1.09$, some subjects have a positive willingness to pay. Assume i is one of them, then, he/she prefers a payoff distribution where $(\pi_i, \pi_j) = (P - wtp_i, 0)$ than a distribution where $(\pi_i, \pi_j) = (P, 0) = (10, 0)$. In terms of Fehr & Schmidt's utility function, this means that:

$$(P - wtp_i) - \alpha_i 0 - \beta_i \max\{(P - wtp_i) - 0, 0\} > 10 - \alpha_i 0 - \beta_i \max\{10 - 0\}.$$

That is, $\beta_i > 1$.

²³This result is closely related to Lazear *et al.* [19] statement that a significant part of players choose to exit a dictator game even when playing the game presents potential allocations that strictly Pareto-dominate the exit option. Notwithstanding this relation, our results in the DG_{exit} have to be interpreted in different terms than those of Lazear *et al.* [19]. The reason is that the chance of quitting the game in our DG_{exit} implies cancelling a decision which results in an extremely unequal payoff distribution, rather than avoiding an environment which permits sharing.

part of their payoff to prevent their previous decision from being put into practice.²⁴

Table 6: MAIN RESULTS IN T4

AMOUNT ACCEPTED TO EXIT							
	n	Mean	Not exit	10	9	8	7
DG _{exit}	22	8.91	3(14%)	7(32%)	4(18%)	4(18%)	4(18%)

BDE also replicates the DG_{exit} with dictator’s friends as recipients. The average amount agents accept to exit the game is very close whether recipients are friends or strangers (8.68 vs. 8.91) and observations are distributed in a similar way.²⁵ Thus, our results seem to be robust to variations.

Going back to the questionnaire, we also asked the participants about the exit option. In particular, we focused on the following salient result. In the DG_{exit}, 3 out of 22 decision makers revealed their preference for not exiting the game; i.e. 14% of the subjects wanted their Decision 1 to be put into practice, admitting the payoff distribution: $(\pi_i, \pi_j) = (P, 0)$. Another 7 individuals (i.e. 32%) preferred to exit the game and cancel their previous decision, but they were not ready to pay anything for exercising this option.

As far as the decision maker’s payoff is concerned there is no difference between these two decisions: in both of them, he/she gets the whole pie. In addition, neither of them implies loss of efficiency. Furthermore, inequity is the same in practice: recipients get zero in both cases. However, there might be a difference: when subjects pay nothing for exiting but choose this option, they might be avoiding γ_2 , i.e., their responsibility for the result. In other words, it could be a clear case of looking the other way.²⁶

To check this, we asked the participants in the questionnaire to answer which of the following games they prefer:

²⁴In Dana, Cain & Dawes [10], about 30% of the decision makers chose to exit a \$10 dictator game in exchange for \$9.

²⁵When recipients are dictators’ friends in DG_{exit}, 5 out of 22 subjects chose “Not exit”, 8 subjects accepted 10 ECUs; 5 subjects, 8 ECUs; 1 subject, 7 ECUs; and 3 subjects, 5 ECUs or less.

²⁶This type of behavior has been called *strategic ignorance* in the literature (see Dana *et al.* [11]): deciding to remain ignorant of the consequences of one’s actions.

- *Game 1: You get 10, your recipient gets 0.*
- *Game 2: You get 10.*

Sixteen subjects out of 21 opted for Game 2. Among these, five subjects (24% over 21) stated that their main concern was their own payoff and added that they did not care about “the other player’s payoff”. They interpreted Game 2 as if there were a fictitious player and his/her earnings were an unknown quantity. On the other hand, seven subjects (33%) explicitly stated that choosing Game 2 implies the possibility that the unknown payoff of this second fictitious player may be positive; that is, they revealed the following preference over payoff distribution: $(10, x) \succ (10, 0)$, where $x > 0$.

In short, more than half the participants in the questionnaire opted for Game 2 as a result of assuming that in this game there is a second player whose payoff is an unknown quantity.

This result may provide some support for our discussion concerning γ_1 and γ_2 : agents prefer not to assume responsibility for mean decisions which they dislike (for instance, giving a zero payoff to his/her recipient for sure) and this fact is affecting their *wtp*.

6 Conclusion

We have shown that the social features of the game such as responsibility in decision making and personal involvement in the decisions’ outcomes are relevant in explaining the motivation behind giving in allocation decisions.

In particular, our analysis takes as a starting point a situation of radical inequity which decision makers can balance at a cost. Their willingness to pay to do so is analyzed under different contexts differing in the guilt feelings which subjects may experience.

Our main conclusion is that benefitting from and feeling responsible for unfair decisions influence subjects’ willingness to pay. Indeed, although in our experiment giving not only corrects inequity but it also generates a greater joint welfare, decision makers’ willingness to pay decreases when the moral costs motivations behind giving are lacking.

Appendix 1: Instructions concerning the payment card in $T1$, $T2$ and $T3$.

At this stage, you have the opportunity to modify your previous decision.²⁷ Unfortunately, this option is not free. If you want to use it, it will cost you something. This cost will be subtracted from your final payoff (if you wish, you can check the decision you made before). Let us focus on Decision 1.

Pay attention to the following table. How should you read this table? 1 point means that YOU give up 1 point so that 10 points are given to the student who got 0 points in your Decision 1; 2 points means that YOU give up 2 points so that 10 points are given to the student who got 0 points in your Decision 1, and so on.

Only one of the rows of the table will be put into practice. This row will be chosen randomly, i.e. by drawing lots. Thus, if in row ten you choose to pay 10 so that the other student gets 10 points and this row is randomly selected, we will reduce your final payoff by 10 points and will give 10 points to the student who got 0 POINTS in your Decision 1.

In each scenario (row), you must mark what you want with a cross. YOU MUST NOT MARK “YES” AND “NO” IN THE SAME ROW (otherwise, you will lose everything).

**If you give up: We give to the student who
got 0 in your Decision 1:**

1 point	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
2 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
3 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
4 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
5 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
6 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
7 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
8 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
9 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
10 points	10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>

²⁷This “previous decision” is Decision 1 in Figure 1. Specifically, it is an *all-or-nothing* dictator game in $T1$; and an *all-or-nothing* allocation decision in $T2$ and $T3$.

Appendix 2: Instructions concerning the payment card in T4.

At this stage, we give you the opportunity TO EXIT THE EXPERIMENT and thus PREVENT DECISION 1 FROM BEING PUT INTO PRACTICE. In other words, you can get points without facing an allocation decision.

To put it differently, we offer you points for not implementing your previous decision (if you wish, you can check the decision you made before).

To learn how we provide you with this opportunity to exit the experiment, pay attention to the following table. How should you read this table? If you choose "YES" at the level where we offer you 1 point, YOU get 1 point and your previous decision is not put into practice; if you choose "YES" at the level where we offer you 2 points, YOU get 2 points and your previous decision is not put into practice, and so on. Remember that if you choose "NO" at all levels, your Decision 1 is executed.

Only one of the rows of the table will be put into practice. This row will be chosen randomly, i.e. by drawing lots. Thus, if you choose "YES" in a certain row and that row is randomly selected, we will give you the amount of points corresponding to that row. If you choose "NO" in the randomly selected row, what you decided in Decision 1 is put into practice.

In each scenario (row), you must mark what you want with a cross. YOU MUST NOT MARK "YES" AND "NO" IN THE SAME ROW (otherwise, you will lose everything).

If we offer you:	You agree to exit:	
1 point	Yes <input type="checkbox"/>	No <input type="checkbox"/>
2 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
3 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
4 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
5 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
6 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
7 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
8 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
9 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
10 points	Yes <input type="checkbox"/>	No <input type="checkbox"/>
